Abstract. We have done a robust statistical analysis of UBV color profiles of 257 Sbc barred and unbarred galaxies. We found that there is an excess of barred galaxies among the objects with null or positive (bluish inward) color gradients, which seems to indicate that bars act as a mechanism of homogenization of the stellar population along galaxies. Moreover, the relationship found between total and bulge colors shows that, in the process of homogenization, the stellar population of bulges are getting bluer, whereas the total color of galaxies remains the same. These characteristics are expected in a secular evolutionary scenario, and seem incompatible with both the monolithic and the hierarchical scenarios for spiral galaxy formation.

1. Color Gradients in Late-Type Barred Galaxies

We estimated $(B - V)$ and $(U - B)$ color gradients, as well as total and bulge mean colors, for each galaxy of a sample of 257 barred and unbarred Sbc systems, using the catalog of Longo & A. de Vaucouleurs (1983,1985), which presents photoelectric aperture photometry data. The gradients were calculated through robust statistical methods, which consist essentially in applying the Least Median of Squares regression (Rousseeuw 1984). Moreover, we have done a comparative photometric study through CCD images to attest the validity of the results obtained.

Our results, considering only face-on galaxies, indicate that $\sim 59\%$ of late-type galaxies have negative color gradients, $\sim 27\%$ have no gradients, and $\sim 14\%$ have positive gradients. Furthermore, there is an excess of barred galaxies among systems with zero or positive color gradients (Table 1). Thus, it seems that bars act as a mechanism of homogenization of the stellar population along late-type galaxies, a result which puts in trouble the monolithic scenario of Eggen, Lynden-Bell, & Sandage (1962).

2. Blue Bulges

We found a correlation between total and bulge colors, which is a consequence of an underlying correlation between the colors of bulges and disks found by other authors (Peletier & Balcells 1996). Moreover, one can see in Table 1 that the mean total color is approximately the same irrespective of the gradient regime,

Table 1. Distribution of the face-on galaxies in our sample in relation to the three regimes of gradients, with the median of their bulge and total mean colors.

Gradient	Color	N	Sample	Barred	Bulge	Total
		(1)	(2)	(3)		
Negative	$(B - V)$	78	63%	75%	0.74 ± 0.01	0.53 ± 0.01
Null		32	26%	91%	0.57 ± 0.02	0.57 ± 0.02
Positive		14	11%	72%	0.36 ± 0.03	0.55 ± 0.05
Negative	$(U - B)$	55	53%	73%	0.24 ± 0.03	-0.05 ± 0.02
Null		30	29%	83%	-0.05 ± 0.03	-0.05 ± 0.03
Positive		19	18%	90%	-0.31 ± 0.07	0.05 ± 0.07

Note. — (1): number of galaxies in each regime; (2): fraction of the sample in each regime; (3): fraction of barred galaxies in each regime.

while bulges are systematically bluer in galaxies with null or positive gradients. These results seem to indicate that bars act changing the color of bulges due to secular dynamical processes (see, e.g., Friedli & Martinet 1993), turning these bulges bluer, while disks are getting redder as a consequence of passive evolution. These effects are expected in the secular evolutionary scenario, but they are not consistent with the monolithic and hierarchical scenarios (e.g., Kauffmann, Guiderdoni, & White 1994) for spiral galaxy formation.

3. Further Results

We also found no correlation between color and chemical abundance gradients, suggesting that the color gradients are more sensitive to the age rather than to the metallicity of the stellar population. Further results and details will appear in a forthcoming paper (Gadotti & dos Anjos, in preparation).
