## ABSTRACT

We present Keck II spectroscopy of an optical mHz quasi-periodic oscillations (QPOs) in the lightcurve of the X-ray pulsar binary Hercules X-1. In the power spectrum it appears as ‘peaked noise’, with a coherency  $\sim 2$ , a central frequency of 35 mHz and a peak-to-peak amplitude of 5%. However, the dynamic power spectrum shows it to be an intermittent QPO, with a lifetime of  $\sim$ hundred seconds, as expected if the lifetime of the orbiting material is equal to the thermal timescale of the inner disk. We have decomposed the spectral time series into constant and variable components and used blackbody fits to the resulting spectra to characterise the spectrum of the QPO variability and constrain possible production sites. We find that the spectrum of the QPO is best-fit by a small hot region, possibly the inner regions of the accretion disk, where the ballistic accretion stream impacts onto the disk. The lack of any excess power around the QPO frequency in the X-ray power spectrum, created using simultaneous lightcurves from *RXTE*, implies that the QPO is not simply reprocessed X-ray variability.

**Key words:** accretion, accretion discs - binaries: close - stars: individual: Hercules X-1 - X-rays: stars

## 1 INTRODUCTION

Hercules X-1/HZ Herculis belongs to the sub-class of LMXBs known as X-ray pulsar binaries. Hercules X-1 is a  $1.4 M_{\odot}$  neutron star with a 1.24 s spin period. It is in a 1.7 day binary orbit with its  $\sim 2M_{\odot}$  companion star, HZ Herculis. Due to the high inclination of the system,  $i \simeq 85^{\circ}$ , it shows deep eclipses on the orbital period.

The variability of Hercules X-1 has been very well studied at all wavelengths. In the X-rays the spin of the neutron star is observed, modulated by the orbital eclipses and a third 35-day cycle. This 35-day X-ray periodicity was first

discovered by Tananbaum et al. (1972) using the *UHURU* satellite as on X-ray on-state followed by an extended off-state. Jones & Forman (1976) later reported a weaker short-on state during the off-state. The 35-day periodicity consists of a main-on state, lasting about 10 days, and a short-on state lasting 5 days, separated by periods where the X-ray flux drops to almost zero (Scott & Leahy 1999). The X-ray pulsations are clearly seen in the X-rays during the on-states but appear with a much lower amplitude during the off states, as expected if the cycle is caused by the obscuration of the central regions of the accretion disk. The evolution of the pulse profile between and during these on-states has been well studied but the origins and evolution of its complex structure remain poorly defined.

While the existence and form of the 35-day cycle is well

\* National Research Council Associate

† Universities Space Research Association

documented, the mechanism responsible is less well understood. It is thought to be caused by a warped, precessing accretion disk that occults the neutron star at certain disk phases. Pringle (1996) showed that a strongly irradiated accretion disk is unstable to warping. The radiation pressure acting on the inner regions of the accretion disk forms a warped precessing accretion disk as seen in Hercules X-1 (Maloney & Begelman 1997; Wijers & Pringle 1999). One other model is that the warp in the disk can be formed by an X-ray driven coronal wind (Schandl & Meyer 1994). In this model, the X-rays from the central compact object irradiate the inner regions of the accretion disk and produce a hot corona, when the sound velocity of the gas exceeds the escape velocity of the potential well the material leaves the binary as a coronal wind, exerting a repulsive force on the disk. Schandl & Meyer (1994) showed that, with suitable boundary conditions, they could create a suitable warp to explain the general features of the 35-day cycle. This model can also explain the observed anomalous and pre-eclipse dips as an interaction of the accretion stream with the warped disk, causing disk thickness increases that temporarily obscure the line of sight to the X-ray source, causing a dip in the X-ray flux (Schandl 1996).

At optical wavelengths, much of the light is due to X-ray heating of the inner face of the companion star and other regions of the binary. This effect is seen to modulate on the binary phase and with the 35-day super-period, implying that the companion star is irradiated even during the observed X-ray off states. The most notable evidence for reprocessing of X-rays on the companion star of Hercules X-1 comes from the observed optical pulsations (Middleditch & Nelson 1976).

We have found a series of low frequency optical Quasi-Periodic Oscillation (QPO) with a central frequency of 35 mHz. These QPOs have also been observed in the UV (Borison et al. 2000) with a frequency of 45 mHz. While these observations are not simultaneous with the optical data presented here, the similarity of the frequencies implies a similar production mechanism. QPOs have been observed in many binary systems, most noticeably in the X-ray observations of both persistent and transient X-ray binaries. In Z-sources, such as Scorpius X-1 and Cygnus X-2, the QPOs are seen to change in both frequency and power as the mass transfer rate onto the compact object changes (Hasinger & van der Klis 1989). In transient sources similar X-ray QPOs are seen. The transient X-ray pulsar, XTE J1858+034 shows 110 mHz QPOs with an RMS amplitude of 3.7-7.8 %. Chakrabarty (1998) found both X-ray and optical QPOs in the X-ray pulsar 4U 1626-67, with a frequency of 48 mHz. The optical QPO in this system is most likely due to reprocessing off the innerface of the strongly irradiated companion star of an X-ray QPO. This X-ray QPO is possibly caused by 'blobs' on Keplerian orbits outside the corotation radius of the neutron star (Kommers, Chakrabarty & Lewin 1998).

In this paper we describe the optical characteristics of the QPO, in order to constrain the position of the region in the binary producing the variability and infer possible production mechanisms.

Parameter	Start	End
UT	07:40	08:50
MJD	51000.32018	51000.36879
Binary phase	0.407	0.435
35-day phase	0.524	0.526

**Table 1.** Summary of optical observations. The binary phase is calculated using the ephemeris of Deeter et al. (1991) and the 35-day phase uses the ephemeris from (Still et al. 2001).

## 2 OBSERVATIONS

The optical data was taken on 1998 July 6, using the Low Resolution Imaging Spectrograph (LRIS; Oke et al. (1995)) on the 10-m Keck II telescope on Mauna Kea, Hawaii. A summary of the observations is given in Table 1. The LRIS was used with a 5.2 arcsecond slit masked with aluminized mylar tape to form a square aperture. The 300/5000 grating used has a mean dispersion of 2.55 Å/pixel in the range 3600 Å - 9200 Å. We used a novel data acquisition system to obtain more than 58,000 spectra of Hercules X-1, in the form of a continuous byte stream. The mean integration time was measured to be 72.075ms and there is no dead-time between individual spectra. In addition to the 2048-pixel spectrum, 25-pixel under-scan and 75-pixel over-scan regions were used to measure the CCD bias level, which we subtracted from each spectrum. The noise for a given pixel was calculated using a readout noise of 6.3 e<sup>-</sup> and a gain of 4.7 e<sup>-</sup>/ADU. Cosmic rays were rejected with a threshold of 10-sigma from the de-biased frames. A master flatfield image was created by finding the median of 700 individual flatfield spectra. This image showed no deviations above 0.3 % in all but 3 pixels. It was decided that it was therefore not necessary to flatfield individual spectra. Calibration arc spectra and spectra of the sky in the region of the object were taken at regular intervals.

The background sky spectrum, which accounts for ~ 0.9% of the total flux was subtracted using the best fit sky spectrum. Sky spectra were taken at the beginning and end of the run, so that long timescale variations could be detected. The mean and variable components of the sky spectrum were found by creating a lightcurve for each pixel and extracting the mean and gradient of this lightcurve. These coefficients were then filtered in wavelength, with a running median filter of width 101 pixels. The gradient of the data was found to be almost zero, as the sky brightness didn't change noticeably during the run. The arc calibration was done by fitting a second order polynomial to 7 lines in a median spectra of exposures of Hg and Ar lamps. Arc spectra from the beginning and end of the run were used to take into account any drifts in the wavelength scale. The wavelength calibration was applied using the MOLLY spectral analysis package. The individual spectra were flux calibrated using exposures taken of the standard star, Feige 56 (Oke 1990). A low order polynomial fit was found to the median of all the individual flux star spectra and this calibration was again applied using MOLLY.

## 2.1 Time calibration

Due to the nature of the continuous stream of data, it was impossible to attach accurate timemarks to each individual spectrum. Individual time marks, accurate to approximately 200-ms, were placed after every other spectrum using the computer clock. In order to establish an absolute time reference, secondary timestamps were obtained on many occasions during the 5-night observing run. To create these timestamps, an incandescent lamp that illuminated the CCD was modulated in synch with radio broadcast time signals. From these we found an ephemeris and mean exposure time. These were checked against the computer's time marks and found to be in excellent agreement.

In order to increase the signal to noise of the individual spectra and make the data-set more manageable, 7 individual spectra were binned together to give 9484 binned spectra with a time resolution of 0.5045 seconds.

## 2.2 X-ray observations

The observations took place on 1998 July 6, using the PCA onboard *RXTE*. Lightcurves were created from the E\_250US\_128M\_0.1s mode data-set. The energy range of the PCA is 2-100 keV. The lightcurves were corrected to the solar-system barycentre, using the subroutine FXBARY in the FTOOLS software suite. They were also corrected for the motion of the neutron star in its binary orbit around its  $2.2M_{\odot}$  companion HZ Herculis, using the orbital ephemeris of Still et al. (2001).

## 3 RESULTS

The continuum lightcurve created from our optical dataset, in the wavelength range 5000Å - 5800Å, is shown in the upper panel of Figure 1. A subset of this lightcurve, clearly showing the QPO is shown in the lower panel of Figure 1.

We used two methods, one temporal and one spectral, to characterise the variability of the source. We created power spectra of the source to determine the temporal characteristics of the variability, then we used this information to determine the spectral characteristics by means of a variability spectrum.

### 3.1 The power spectrum

We created power spectra for the total data-set by simple sine-curve fitting to the input lightcurve, in a method analogous to the Lomb-Scargle periodogram (Press & Rybicki 1989). However in our method, optimal weights were applied when fitting each sine-curve. This method was preferred to fast Fourier transforms (FFTs) due to the presence of irregular gaps in the data. The resulting power spectrum is shown in Figure 2. The power spectrum was represented as a sum of three terms; (1) white noise power at all frequencies, (2) a 'red noise' power-law describing the intrinsic flickering of the source, and (3) a hump-like peaked noise feature, caused by the summation of the individual transient QPOs, described as a Gaussian. These features can be described numerically as,

$$P(f) = P_{wn}(f) + P_{pl}(f) + P_{qpo}(f)$$

**Figure 1.** Top panel, lightcurve of the optical variability in Hercules X-1 for the entire data-set. Bottom panel, lightcurve of a subset of the data clearly showing the QPO. The units of flux density are mJy in the wavelength range 5000 - 5800 Å. Each data point is the average of approximately 7 individual spectra. No error bars are shown in the top panel for clarity.

$$\begin{aligned}
 &= P_{wn} \\
 &+ P_{pl} \left( \frac{f}{f_p} \right)^{-\alpha} \\
 &+ P_{qpo} \exp \left[ -\frac{1}{2} \left( \frac{f - f_0}{\Delta f} \right)^2 \right],
 \end{aligned} \tag{1}$$

Parameter	unit	value
$P_{wn}$	$10^{-3} \text{ mJy}^2 \text{ Hz}^{-1}$	$5.09^{+0.14}_{-0.15}$
$\alpha$		$2.25^{+0.13}_{-0.18}$
$P_{pl}$	$10^{-3} \text{ mJy}^2 \text{ Hz}^{-1}$	$12.0^{+1.4}_{-1.4}$
$P_{qpo}$	$10^{-3} \text{ mJy}^2 \text{ Hz}^{-1}$	$49.30^{+10.4}_{-7.1}$
$f_0$	mHz	$35.2^{+4.3}_{-8.1}$
$\Delta f$	mHz	$17.4^{+3.7}_{-2.6}$
Integrated QPO Power	$10^{-2} \text{ mJy}^2$	$21.5^{+6.4}_{-4.5}$

**Table 2.** Best-fit values to model for power spectrum of total dataset, shown in Equation 1. The best fit  $\chi^2$  was 7410.15 for 4687 degrees of freedom.

where  $P_{wn}$  is the power of the white noise level,  $P_{pl}$  is the power at  $f_p$ , fixed to be 0.1 Hz, of the ‘red noise’ power-law with spectral index  $\alpha$ .  $P_{qpo}$  is the peak power of the Gaussian QPO feature with a central frequency  $f_0$  and standard deviation  $\Delta f$ . (Note: while a lorentzian is normally used to characterize a QPO, we have reverted to using a Gaussian to characterize the randomness of the position of the central frequencies of the individual QPOs)

The coherence if the QPO is low,

$$Q = \frac{f_0}{\Delta f} \sim 2, \quad (2)$$

suggesting that the sinusoidal components change period, phase or amplitude substantially in just a few cycles, as can be seen in the bottom panel of Figure 1.

The best fit values of the free parameters are shown in Table 2. These were found using an amoeba code to search through the parameter space, see Press et al. (1992) for a discussion of amoeba codes. The best fit has a  $\chi^2$  of 7410.15 for 4687 degrees of freedom. We determined the 1-parameter 1-sigma confidence regions for each parameter by fixing a parameter and then optimising the fit until the badness of fit is equal to  $\chi^2_{aim}$ .  $\chi^2_{aim}$  is determined using the value of  $\chi^2_{min}$ , where,

$$\chi^2_{aim} = \chi^2_{min} + \frac{\chi^2_{min}}{N - P}, \quad (3)$$

where  $N - P$  is the number of degrees of freedom in the fit.

### 3.2 Dynamic power spectrum

We used the Gabor transform (Heil & Walnut 1989,1990) to create dynamic power spectra to investigate the time evolution of the power spectrum determined from our optical data. This is especially valuable due to the low coherency of the oscillations, to determine if the low coherency is caused by the evolution of the central frequency of the oscillation, perhaps caused by material rapidly moving through the inner regions of the accretion disk, or whether the low coherency is caused by randomly occurring events based around a central frequency, as would be the case for short-lived blobs of material on Keplerian orbits within the disk.

The discrete Gabor transform is a wavelet transform that allows us to determine the power spectrum over a subset of the data, using a Gaussian window on the lightcurve (Boyd et al. 1995). We have chosen the 3-sigma width of the

**Figure 4.** The X-ray power spectrum for our RXTE observations, simultaneous with the optical observations. The power spectrum has been normalised, following the method of Leahy et al. (1983), and the Poisson level has been removed. The power spectrum shows no evidence for excess power in the region of the optical QPO. However an excess of power is clearly seen at 0.01 Hz.

window to be 750-s. The data set contained 9484 data points, which have been filtered with a running median filter with a filter width of 101-s to remove the slowly varying component. For computational purposes, the resulting lightcurve was padded with 6900 randomly distributed points with the same mean and variance as the data set. The results of this analysis are shown in Figure 3, where the main image shows the results of the Gabor transform, the lower panel shows the integrated power at a given time and the right-hand panel shows the average power spectrum.

The dynamic power spectrum shows transient QPOs in the frequency range of the peaked noise feature. While there is little evidence of frequency evolution of the individual features, it is possible that the feature that appears at  $\sim 15$  mHz at  $T = 2800$ -s, evolves into the feature at  $\sim 46$  mHz at  $T = 4500$ -s. From the coherency of the individual QPOs, we see that the average lifetime of the features is 200-300-s, or ten times the Kepler period of the features.

### 3.3 A reprocessed X-ray QPO ?

In order to determine if the optical QPO is a reprocessed version of an X-ray QPO, we calculated power spectra of the X-ray data simultaneous with our optical data. We chopped the total X-ray lightcurve into 512-s sections and created individual Leahy-normalised power spectra (Leahy et al. 1983) for each lightcurve. We then combined the separate power spectra to create a total power spectrum for the observations. This method is more successful at determining the power in the QPO, which spans a broad range of frequencies and is only coherent on short timescales.

The average power spectrum, shown in Figure 4, shows no evidence for the QPO at 35 mHz, implying the optical

**Figure 2.** Top, the binned power spectrum for the total dataset, showing the best fit model (solid line), with a reduced  $\chi^2 = 1.581$  for 4687 degrees of freedom. The white noise, power law and QPO components (dashed lines) are also shown based on their best fit parameters. Bottom, the residuals of the fit, showing the full resolution of the power spectrum.

QPO is not simply an X-ray QPO that is reprocessed into an optical flux by some region in the binary. However there is evidence for some excess power at 0.01 Hz, which is possibly the X-ray counterpart of our slow variability.

### 3.4 The spectrum of the variability

We created variability spectrum-lightcurve pairs that, when re-combined, reproduce the entire spectral time series, using

a method similar to that used by Eracleous & Horne (1996) to decompose the flaring and quiescent spectra of AE Aqr. The model of the spectral time series,  $M(\lambda, t)$ , is written as,

$$M(\lambda, t) = S_0(\lambda) + S_1(\lambda) L_1(t) + S_2(\lambda) L_2(t), \quad (4)$$

where  $S_0(\lambda)$  is the average spectrum,  $S_1(\lambda)$  and  $L_1(t)$ , are the spectrum and lightcurve of the first variable component and  $S_2(\lambda)$  and  $L_2(t)$  are the spectrum and lightcurve of the second variable component.  $L_1(t)$  and  $L_2(t)$  are normalised to a mean value of zero and unit variance. This normalisation

**Figure 3.** Results from performing a Gabor transform on the filtered optical dataset. The main panel shows the dynamic power spectrum. The right-hand panel shows the average power spectrum and the lower panel shows the integrated power as a function of time.

ensures that the spectral components  $S_1(\lambda)$  and  $S_2(\lambda)$  have units of mJy and do not contribute to the time averaged spectrum.

The model is compared to the observed spectral time series and the badness of fit calculated using a  $\chi^2$  analysis. We solved iteratively for each component of the model, until a suitable convergence criterion was met, namely that the percentage change in the global  $\chi^2$  was less than 0.1% over 3 successive iterations. In order to check that a global minimum had been reached, we chose several different sets of initial values, each of which converged onto the same final values.

In order to separate the variability into slow and fast components we filtered the lightcurves, using Savitzky-Golay filters (Press et al. 1992) of different widths. We low-pass filtered the lightcurve  $L_1(t)$  to remove variations faster than 80-s. This component then measures primarily the red noise power-law component identified in the power spectrum. Similarly we low-pass filtered the lightcurve  $L_2(t)$  to remove variations faster than 5-s, which are primarily the white noise component. This means that  $L_2(t)$  responds to variations between 80-s and 5-s, which include the tail of the red noise and the QPO.

The results of the fit to the spectral time series are shown in Figure 5. In the first variability lightcurve,  $L_1(t)$

the fluctuations seen with frequencies around 10 mHz are resolved. The spectrum of this variability,  $S_1(\lambda)$ , is bluer than the average spectrum,  $S_0(\lambda)$ . The rms amplitude of this variable component increases from 1% of the mean flux at the red end of the spectrum to 2% at the blue end. The second variability lightcurve,  $L_2(t)$ , shows the variability of the 35 mHz QPO. The features are transient, showing the QPO is not coherent over more than a few cycles. The spectrum of this variable component,  $S_2(\lambda)$ , has an rms amplitude of 0.5 % at the red end of the spectrum to 1 % in the blue. The spectral features in the two variability spectra are very similar. The Balmer lines appear to be narrower than in the average spectrum, implying they have variable wings, while the cores of the lines vary less than the average spectrum. The NII + CII blend at 4641 Å also appears to show a strong variable component. This line is interesting as it is a blend of two lines formed by Bowen fluorescence (Schacter, Filippenko & Kahn 1989) and is thought to be caused by irradiation of the binary by the central X-ray source. In contrast the He II line at 4685 Å is not apparent in either variability spectrum, implying that it is not highly variable.

These results agree well with the power spectra analysis in the previous section. The average flux in the second variability lightcurve, shown in the third panel in Figure 5, is in good agreement with the flux in the QPO and the variability lightcurve shows variability on the same timescales as the QPO period. We conclude from this that the second variability spectrum,  $S_2(\lambda)$ , represents the spectrum of the QPO.

### 3.5 Spectral fits to variability spectra

The next stage of the analysis was to fit model spectra to the data to fit physical parameters to the observed average and variability spectra from the previous analysis. To do this we used two models to see which best represents the data. Both models use blackbody spectra to describe the observed continuum fluxes.

#### (i) A single blackbody:

This will tell us the temperature and size of the emitting region. The model spectrum is defined at a wavelength  $\lambda$  as,

$$F_\nu(\lambda) = \frac{\pi R^2}{D^2} B_\nu(\lambda, T) \quad (5)$$

for a region with a radius,  $R$ , a temperature,  $T$ , at a distance  $D$ . This model is most useful for a region that has a roughly constant temperature for the duration of the observations.

#### (ii) The difference of two blackbodies:

The second model is fitting the difference of two blackbodies to the data. This involves fitting the difference of two blackbodies with different temperatures,  $T_1$  and  $T_2$ , where  $T_2 > T_1$ . The model spectrum is defined at a wavelength  $\lambda$  as,

$$F_\nu(\lambda) = \frac{\pi R^2}{D^2} [B_\nu(\lambda, T_2) - B_\nu(\lambda, T_1)] \quad (6)$$

for a region with a radius,  $R$ , at a distance  $D$ . This model is most useful for describing a region whose temperature varies during the observations. These variations are limited to coming from the same region, ie a single region where the temperature varies between  $T_1$  and  $T_2$ .

These models were fitted to regions of the spectra that are least contaminated with lines. The best fit values, together with their 1-parameter 1-sigma confidence regions are shown in Table 3. The data together with the best fit models and the regions used are shown in Figure 6. The value of  $\chi^2$  is large in all three cases, due to the high signal-to-noise of each spectrum revealing intrinsic deviations from a Blackbody. However, with the confidence intervals re-scaled as shown in Equation 3, the parameters remain reasonably well constrained.

## 4 DISCUSSION

We have studied the X-ray and optical variability in the accreting pulsar Hercules X-1 and found evidence for a series of optical QPOs that comprise a broad peaked noise feature in the overall power spectrum. While the coherence of this feature is low,  $Q \sim 2$ , the individual QPOs that comprise the peak have much higher coherencies, as seen in the lightcurve in the lower panel of Figure 1 and the widths of the features in the dynamic power spectrum. We have characterised this noise feature as having a Gaussian shape in the power spectrum. This has been fitted along with the white noise level and a power law to describe the variability of Hercules X-1 at low frequencies. The best fit to this model has a peak frequency of 35.2 mHz.

We have extracted the spectrum of the variability from the frequency range of the QPO. We have also determined the average spectrum and the spectrum of any slower variability, that has characteristic frequencies from the red noise, power-law region of the power spectrum, as shown in Figure 5. The variability spectra are bluer and fainter than the average spectrum, indicating they are from small, high temperature regions. The average spectrum is predominantly that of the companion star, HZ Herculis. It shows strong absorption in the Balmer lines, as well as some He I absorption lines. There is some evidence of the irradiation of the companion in the form of a weak He II ( $\lambda 4686$ ) emission line and Bowen fluorescence lines ( $\lambda 4634$ ,  $\lambda 4641$ ,  $\lambda 4642$ ), which can be used as a diagnostic of the physical conditions in the binary (Schacter, Filippenko & Kahn 1989). The variability spectra both show a bluer continuum than the average spectrum with Balmer and Helium I absorption lines, however in these spectra the wings of the lines show more variability than the cores. The Bowen lines also show more variability than the average spectrum, as expected if the variability is coming from a region that has been heated by the irradiation of the X-ray source.

Our simple blackbody fits to the observed spectra, while not particularly physical, enable us to constrain models for their production. The best fit model to the average spectrum is a single temperature blackbody, with a mean temperature of 16500 K. The size of the emitting region is  $8.6 \times 10^{22}$  cm<sup>2</sup>. While this temperature is inconsistent with the temperature of the companion star in the absence of irradiation, which has been observed during eclipse of the accretion disk to have a temperature of  $\sim 7000$  K, it is most likely to be due to the strongly irradiated inner face of the companion star. The size of emitting region would cover approximately 70% of the innerface of the companion star, assuming a distance

**Figure 5.** Top panels, the average spectrum,  $S_0(\lambda)$ , (left) and its associated lightcurve (right), which is set to be unity. Centre panels, the first variability spectrum,  $S_1(\lambda)$ , (left) and its associated lightcurve,  $L_1(t)$ , (right). Bottom panels, the same as above for the second component of the variability. Typical error bars are shown on the spectra. The first variability lightcurve is detrended and filtered with a width 40-s. The second variability lightcurve is filtered with a width of 5-s.

of 5 kpc and an effective Roche lobe radius of  $3.5 \times 10^{11}$  cm (Eggleton 1983).

The best fit model to the variability spectra of the slowly varying component also enable us to place constraints on the size and possible locations of the emitting region. The slowly varying component is best fit with the derivative of a blackbody model, although the single temperature blackbody is almost as good a fit. In this model the source varies between 7600 K and 31000 K, from a region of  $3.6 \times 10^{20}$  cm<sup>2</sup>. One candidate for this component is the same region on the companion star as the average spectrum, but with

a smaller area, possibly the most highly irradiated regions close to the inner Lagrangian point.

The best fit model to the spectrum of the QPO is that of a single temperature blackbody with a mean temperature of  $\sim 33600$  K, with an area of  $1.6 \times 10^{20}$  cm<sup>2</sup>. The data is not consistent with the model of a derivative of a blackbody as used to describe the slowly varying component. The fit converges to almost the same solution as with the single temperature Blackbody. This leads us to consider whether or not the QPO is produced in a physically distinct region from that of the slowly varying component. The QPO pro-

$\chi^2/99$		9107	3.904	2.996

**Table 3.** Summary of best fit parameters to the spectral fitting of the spectra from the variability model, together with their 1-parameter 1-sigma confidence regions. A distance of 5 kpc was assumed throughout.

ducing region is a small, high temperature region, probably in the accretion disk surrounding the compact object. Therefore if the frequency of the QPO is the Kepler frequency of material orbiting around the neutron star, the Kepler radius of the material orbiting with a frequency of 35 mHz around a  $1.3 M_\odot$  neutron star would be  $3.3 \times 10^9$  cm. This would appear to be too small to contain the region responsible for the observed spectrum. However if we take the *range* of frequencies included in the QPO, we find that the Kepler radii covered are  $9.4 \times 10^8 - 5 \times 10^{10}$  cm, which is large enough to encompass the observed region.

The existence of a range of preferred azimuths in the disk explains the observations of the QPO frequencies. There are two mechanisms whereby this anisotropy could cause the observed QPO. The first is the material in the preferred region of the disk is orbiting the neutron star and we are seeing the irradiated innerface of the region, as it passes across the backside of the disk. The second explanation is that the azimuths are fixed in the plane of the binary and that inhomogeneities in the material traveling through these regions gives rise to enhanced emission. This material would orbit the neutron star and emit when it passes through the preferred azimuths.

Schandl (1996) modelled the warp in the accretion disk to explain the occurrence of the anomalous and pre-eclipse dips, using a coronal wind model. In this model it is the variation with synodic period of the penetration depth of the stream into the inner regions of the accretion that accounts for an increase in material along the line of sight to the binary that accounts for the observed dips. The Keck II observations were taken at the synodic orbital phase of 0.894. At this phase the accretion stream can penetrate down to the inner regions of the accretion disk. According to Schandl's calculations at this synodic period the stream will penetrate the disk at a radius of  $\sim 5.1 \times 10^{10}$  cm. This is in excellent agreement with the lowest Kepler frequency of the observed QPO. This model predicts that the thickness of the disk will increase as the stream interacts with the disk. If this energy is dissipated on a thermal timescale, then for a thin disk,  $t_{dyn} \sim \alpha t_{th}$ , so that  $\alpha \sim Q^{-1}$ . Thus our observation that the coherence of an individual feature in the dynamic power spectrum last for  $\sim 10 \times t_{dyn}$  naturally leads to a value of  $\alpha \sim 0.1$ .

Such a model, where the disk-stream interaction point

leads to a blob of material orbiting in the disk, close to the corotation radius, could also explain the observations of the QPO in 4U 1626-67. In this system, the QPO has a similarly low coherence, but is observable over more than a decade (Kommers, Chakrabarty & Lewin 1998), which is easily explained if the accretion stream causes a relatively stable preferred radius in the disk. However in Hercules X-1 we do not observe the QPO in the X-ray lightcurves, as in 4U 1626-67, although this could be due to the viewing angle during the X-ray off state. Observations during the X-ray on state are necessary, with simultaneous optical observations to determine if the optical QPO is indeed a reprocessed X-ray QPO.

## ACKNOWLEDGMENTS

KOB was supported by a PPARC research Studentship for much of this work. We thank John Cromer for writing, testing, and loading the software that allowed the LRIS CCD to read out continuously, and Bob Leach for helpful discussions. We especially thank Tom Bida and Frederic Chaffee for kindly letting us make changes to the LRIS system. Data presented herein were obtained at the W.M. Keck Observatory, which is operated as a scientific partnership among the California Institute of Technology, the University of California and the National Aeronautics and Space Administration. The Observatory was made possible by the generous financial support of the W.M. Keck Foundation. We would also like to thank Peter Jonker for his help with the X-ray power spectrum analysis. This research has made use of NASA's Astrophysics Data System Abstract Service.
