(Dated: October 31, 2018)

We report a detailed study of ¹¹B and ²⁷Al NMR spin-lattice relaxation rates $(1/T_1)$, as well as of ²⁷Al Knight shift (K) of $Mg_{1-x}Al_xB_2$, $0 \le x \le 1$. The obtained $(1/T_1T)$ and K vs. x plots are in excellent agreement with ab initio calculations. This asserts experimentally the prediction that the Fermi surface is highly anisotropic, consisting mainly of hole-type 2-D cylindrical sheets from bonding $2p_{x,y}$ boron orbitals. It is also shown that the density of states at the Fermi level decreases sharply on Al doping and the 2-D sheets collapse at $x \approx 0.55$, where the superconductive phase disappears.

The discovery of superconductivity in MgB₂ attained recently a lot of interest [1], as this binary alloy reveals a remarkably high $T_c \approx 40 \mathrm{K}$. MgB₂ is isostructural and isoelectronic with intercalated graphite (ICG), with carbon replaced by boron, and therefore exhibits similar bonding and electronic properties as ICG. Thus the high T_c value of MgB₂ in comparison to ICG ($\sim 5 \mathrm{K}$) was very surprising.

Band structure calculations [2, 3, 4, 5, 6] have shown that Mg is substantially ionized in this compound, however the electrons donated to the system are not localized on the B anion, but rather are distributed over the whole crystal. The six B p bands contribute mainly at the Fermi level. The unique feature of MgB₂ is the incomplete filling of the two σ bands corresponding to prominently covalent sp^2 -hybridized bonding within the graphite-like boron layer. Two isotropic π bands are derived from B p_z states and four two dimensional σ bands from B $p_{x,y}$. Both p_z bands cross the Fermi level, while only two bonding $p_{x,y}$ bands and only near the Γ point (0,0,0) do so, forming cylindrical Fermi surfaces around Γ -A line. Due to their 2D character, these bands contribute more than 30% to the total density of states (DOS)[2, 4, 7, 8]. Such strong anisotropy in the Fermi surface (and possibly in the electron phonon coupling) conciles with the recently reported anisotropy in H_{c2} [9, 10, 11, 12, 13, 14], and the existence of two superconducting gaps [15, 16, 17, 18, 19, 20, 21].

In view of these important findings, great interest has been raised on measurements of electron or hole doped MgB₂, aiming to clarify how the electron DOS and the Fermi surface depend on doping. A very suitable substitution for such a study is Al, which donates three electrons (instead of two for Mg), and thus doping by one electron per atom. In addition, the end members MgB₂ and AlB₂ as well as the intermediate mixed crystals $Mg_{1-x}Al_xB_2$ crystallize in the P6/mmm space group, whereas by Al doping the lattice constants decrease almost linearly [22]. The similarity of the calculated elec-

FIG. 1: Boron $^{11}(1/T_1T)$ for $Mg_{1-x}Al_xB_2$ as a function of Aldoping. Lines show the ab initio calculated plots from Refs. 4. 8

tronic density of states between MgB₂ and AlB₂ indicates that Al doping results in simple filling of the available electronic states. Suzuki et al. [23] predicted that in $\text{Mg}_{1-x}\text{Al}_x\text{B}_2$ the concentration of σ holes varies with x as $n_h = (0.8-1.4x)\times 10^{22}~\text{cm}^{-3}$, leading to $n_h = 0$ for $x\approx 0.6$. A similar conclusion was deduced in Refs. 3, 4, 24. Under these aspects, the detrimental effect of Al doping on T_c can be explained by the fact that doping increases the Fermi energy (E_F) , while decreasing the DOS $N(E_F)$.

An excellent probe to study the influence of the Al sub-

stitution on the electronic structure of electron doped MgB₂ is nuclear magnetic resonance (NMR). Knight shift, K, and nuclear spin-lattice relaxation (NSLR) rate $1/T_1$ measurements, give us the possibility to determine experimentally $N(E_F)$ through the static and fluctuating parts of the hyperfine field, induced at the position of the resonating nuclei from electrons at the Fermi surface. This allows to estimate the contribution of different atoms to $N(E_F)$ as well as and the anisotropy of electronic states at the Fermi level.

The Hamiltonian describing the magnetic interaction of the nucleus with the atomic electrons can be written as [25]: $\mathcal{H} = 2(8\pi/3)\mu_B\gamma_n\hbar\mathbf{I}\cdot\mathbf{S}(\mathbf{r})\delta(\mathbf{r}) - 2\mu_B\gamma_n\hbar\mathbf{I}\cdot[\mathbf{S}/r^3 3\mathbf{r}(\mathbf{S}\cdot\mathbf{r})/r^5$ $-\gamma_n\hbar(e/mc)[\mathbf{I}\cdot(\mathbf{r}\times\mathbf{p})/r^3]$, where μ_B is the Bohr magneton, γ_n the gyromagnetic ratio, **I** and **S** the nuclear and electron spins respectively, and \mathbf{r} is the radius vector of the electron with the nucleus at the origin. In the formula above, the first term describes the Fermi contact interaction, the second term the spin dipolar interaction between nuclear and electron spins, and the third term the coupling with the electronic orbital moment. In the simplest case, where only contribution from the Fermi contact term is considered, the first term can be rewritten as $\mathcal{H}_{KS} \propto -V(8\pi/3)\gamma_n \hbar \chi_p \langle |\Psi(0)|^2 \rangle_{F_S} \mathbf{I} \cdot \mathbf{H_0}$, where $\chi_p = M/H = \mu_B^2 N_s(E_F)/V$, and the symbol $\langle \rangle_{F_S}$ means the average over all s orbitals at the Fermi surface. Due to this term the nuclear spin I 'sees' an internal field $V\chi_p \mathbf{H_0}/2\mu_B$, which is superimposed on the applied external magnetic field, and causes a paramagnetic shift of the nuclear resonance, i.e. the Knight shift. In a similar way, the relaxation rate from the Fermi contact term is expressed by the relation [25]: $(1/T_1)$ = $(64\pi^3/9)\gamma_e^2\gamma_n^2\hbar^3\langle|\Psi_{\mathbf{k}}(0)|^2|\Psi_{\mathbf{k}'}(0)|^2\rangle_F N_s(E_F)^2k_BT$. A similar dependence on $N_{2p}(E_F)^2$ holds if the nuclear Hamiltonian is dominated by the nuclear-electron orbital interaction [26]. Hence, the dependence of both K and $1/T_1$ on certain partial $N_i(E_F)$ is clear.

Until now, ¹¹B, ²⁷Al and ²⁵Mg NSLR and Knight shift measurements have been reported for pure MgB₂ and AlB₂ [27, 28, 29, 30, 31], which are in agreement with the theoretical predictions. These results, in conjunction with ab initio calculations [4, 7, 8] have shown that in MgB_2 the ¹¹B NSLR is dominated by orbital relaxation, whereas in AlB₂ the ¹¹B NSLR is overruled by the Fermi-contact interaction. On the other hand, ²⁷Al and ²⁵Mg NSLRs, as well as the Knight shift on all three ¹¹B, ²⁷Al, and ²⁵Mg sites was shown to be controled by the Fermi-contact polarization [7, 29]. Besides, ¹¹B-NMR NSLR relaxation rate measurements on mixed $Mg_{1-x}Al_xB_2$, $x \leq 0.2$, have shown a rapid decrease of $1/(T_1T)$ with doping that was attributed to reduction of the total $N(E_F)$ [32]. Nevertheless, a detailed NMR study of the variation of each partial $N_i(E_F)$ with Al doping, and comparison with theory is lacking so far.

The purpose of this work is to report a systematic study of ¹¹B and ²⁷Al NSLR rates 1/T₁, as well as of ²⁷Al

FIG. 2: 27 Al NMR line shapes of the central transition at room temperature for $\mathrm{Mg_{1-x}Al_xB_2}$. For x=0.0125 and 0.025 100, 000 accumulations were acquired, due to the weakness of the signals. In the low doping regime, the spurious signal at +1700 ppm is coming from the probe. The peak at the same frequency for x=0.80, 1.0 is produced by free Al that unavoidably remained during sample preparation. For clarity, all spectra are normalized to one.

Knight shifts, as a function of Al doping for $Mg_{1-x}Al_xB_2$, 0 < x < 1. ¹¹B Knight shift measurements were not considered, because the isotropic ¹¹B Knight shift is small $(+40 \text{ ppm for MgB}_2 \text{ and } -10 \text{ ppm for AlB}_2 [29])$, and of the same order of magnitude with the dipolar and the second order quadrupolar split in the NMR fields 2.35, and 4.7 Tesla that have been used in this work. Our measurements show an excellent agreement between the experimental boron $^{11}(1/T_1T)$ plot with that obtained from local density-functional methods [4, 8], and the dominance of the orbital relaxation up to $x \approx 0.55$, where $T_c(x)$ vanishes. This is a convincing evidence that up to this doping the hole-type 2 - D cylindrical sheets (from bonding $2p_{x,y}$ boron orbitals) of the Fermi surface play an essential role in the ¹¹B NSLR. The slight decrease of both 27 K and $^{27}(1/T_1T)$ for $x \leq 0.55$, and their abrupt increase above this doping value are in support of this conclusion.

Polycrystalline samples of nominal composition $Mg_{1-x}Al_xB_2$ for $0 \le x \le 1$ were prepared by reaction of Al and Mg powders with amorphous B at temperatures between 700°C and 910°C as described elsewhere [14]. We notify that: According to the available literature [22, 33, 34, 35] and our data, the temperature where the reaction (preparation temperature) takes place, defines the shape of the (00l) diffraction peaks in the region

FIG. 3: The 27 K Knight shift of NMR spectra for $Mg_{1-x}Al_xB_2$ in fields 2.35 and 4.7 Tesla.

 $0.05 \le x \le 0.5$. The existence of significant broadening or/and splitting in these peaks manifest the existence of some kind of phase separation in this doping range. (ii) Carefully preparated samples in the region arround x = 0.5 display a broad superlattice peak (001/2) which means that ordering of Mg and Al occurs [36].

 27 Al NMR line shape measurements of the central transition $(-1/2 \rightarrow 1/2)$ were performed on two spectrometers operating in external magnetic fields $H_0 = 2.35$ and 4.7 Tesla. Spectra were obtained from the Fourier transform of half of the echo, following a typical $\pi/2 - \tau - \pi/2$ solid spin-echo pulse sequence. The 11 B T_1 of the central line was determined by applying a saturation recovery technique, and fitting with the two exponential relaxation function that is appropriate for I = 3/2 nuclei [37]. Correspondingly, 27 Al T_1 was determined by applying the three-exponential recovery law that is appropriate for I = 5/2 nuclei [30, 37].

Figure 1 shows the boron $^{11}(1/\text{TT}_1)$ as a function of x, in the normal state. In all cases a single component of T_1 was found to fit satisfactorily the magnetization recovery curves. Besides, a $1/T_1T$ =constant relation was fiting the experimental data from room temperature down to 80K. Our measurements reveale that by increasing doping, $^{11}(1/\text{TT}_1)$ decreases rapidly up to x=0.55, and subsequently exhibits a slight increase for $x \geq 0.55$. For reasons of comparison, we have plotted the calculated $^{11}(1/\text{TT}_1)$ values from Ref. 8, for all three orbital, dipoledipole, and Fermi contact term contributions. Clearly, the orbital term dominates in the ^{11}B relaxation rates for $x \leq 0.55$. In case of pure MgB₂ the ^{11}B orbital hyperfine interaction of 2p-holes with the nuclear magnetic moments is about 3 times larger than the dipole-dipole,

FIG. 4: $^{27}(1/T_1T)$ for $Mg_{1-x}Al_xB_2$ as a function of Al-doping x.

and the Fermi contact interaction. This is due to the fact that the boron p_{σ} and p_{π} bands are all at the Fermi level ($N_{px}=N_{py}\approx 0.035$, $N_{pz}\approx 0.045$ states/eV/spin/B), whereas only a few s boron electrons are close to the Fermi level $(N_s \approx 0.002 \text{ states/eV/B})[7, 29]$. This gives a ratio between the Fermi-contact and the orbital/dipoledipole coupling constants, $F \simeq 0.35$ [7], and $^{11}T_1^{-1}$ is mainly proportional to $N_{2p}(E_F)^2$. It may thus be inferred that the rapid decrease of the ¹¹B relaxation rate is due to decrease of the DOS in the 2-D hole-type sheets, while a minimum $1/T_1$ value is obtained at $0.55 \le x \le 0.60$, where the 2-D sheets appear to collapse. We also notice the discrepancy between the theoretical and experimental values for x > 0.6. Most probably, calculations tend to overestimate the Fermi contact interaction at the position of the B nucleus in this doping range [29].

Figure 2 demonstrates $^{27}{\rm Al}$ NMR line shapes of ${\rm Mg_{1-}}_x{\rm Al}_x{\rm B_2}$ at room temperature in field 4.7 Tesla. A completely similar picture was obtained in field 2.35 Tesla. The spectra for x=0.0125, and 0.025, were extremely weak, and therefore were acquired with 100,000 signal accumulations (for comparison, signals for $x\geq 0.1$ were acquired with 512 accumulations). In all samples the spectra consist of a central transition line, $\approx 20~{\rm kHz}$ wide, which shifts with doping, and a broad powder pattern from the satellite transitions. The low doping spectra exhibit a spurious weak peak at +1700 ppm that was produced by the probe. The strong peak at the same frequency for x=0.80,1.0 is produced by free Al that inavoidably remains during sample preparation at high doping concentrations.

In Figure 3 we show the shift of the central line peak as a function of x, in fields 2.35 and 4.7 Tesla. The sig-

nal of a standard aqueous solution of AlCl₃ was used as reference. The coincidence of the curves in both fields is a clear evidence that the obtained spectral shift corresponds solely to the ²⁷K shift. In typical metallic shifts of I = 5/2 nuclei like ²⁷Al, in addition to the Knight shift, the center-of-gravity position of the NMR signal should include the second-order quadrupole shift given by $\Delta \nu = (25\nu_Q^2)/(18\nu_L)$ [38]. However, recent experiments on AlB₂ have shown that the quadrupolar coupling constant is $\nu_Q \simeq 80$ kHz [29], thus giving a negligibly small second order quadrupolar shift, $\Delta \nu \approx 14$ ppm. According to Figure 3, by increasing x the 27 K decreases rapidly, whereas for x > 0.55, i.e. at the doping value where the superconductive phase disappears [24], it increases sharply becoming $\approx +900$ ppm for pure AlB₂. As previously shown, by Al doping of MgB₂ the σ hole bands are filled [3, 4, 24], and their contribution to $N(E_F)$ becomes zero at $x \approx 0.55$ [24]. Evidently, the gradual decrease of ${}^{27}{\rm K}$ for $x \le 0.55$ reflects, (i) the initial slight decrease of $N_s(E_F)$ in this doping range [2], and (ii) the reduction of the Stoner enhancement by filling the σ hole bands, due to decrease of the total $N(E_F)$. We notice that the Stoner enhancement renormalizes both K and $1/T_1$ by a factor $S = 1/(1 - IN(E_F))^{\alpha}$, with $\alpha = 1$ for K, and $1 \leq \alpha \leq 2$ for $1/T_1$ [7, 8]. On the other hand, the sharp increase of the Knight shift for $x \geq 0.55$, may be attributed to the rapid increase of N_s by further doping, after completely filling the $2p_{x,y}$ hole bands $(N_s(Mg) \text{ in } MgB_2 \text{ is } \approx 0.0092 \text{ states/eV/spin, whereas})$ $N_s(Al)$ in AlB₂ is ≈ 0.0362 states/eV/spin [7]). A similar behaviour is observed in Figure 4, which exhibits the $^{27}(1/TT_1)$ vs. x plot. This is expected as the ^{27}Al relaxation rate is dominated by the Fermi contact interaction, and therefore is proportional to $N_s^2(Al)$ [29].

In conclusion, ^{11}B and ^{27}Al NMR NSLR rate and Knight shift measurements have been employed in order to investigate the structure and the variation of the Fermi surface in MgB₂ upon Al (i.e. electron) doping. Our results are completely consistent with calculations predicting a strongly anisotropic Fermi surface that is comprised from hole-type σ -bonding 2-D cylindrical sheets, and a hole-type and electron-type, 3-D π -bonding tubular network. The collapse of the 2-D sheets at $x\simeq 0.55$, as predicted by theory, is experimentally verified by the fast decrease of the ^{11}B NSLR rate for $x\leq 0.55$ and the sharp increase of both the ^{27}K , and $^{27}\text{NSLR}$ rates for $x\geq 0.55$. The latter indicates a strong reshaping of the Fermi surface towards the electronic structure of AlB₂,

due to interplane electron contribution. Our results concile with both experimental and theoretical evidence that indicate anisotropic pairing and multi-gap superconductivity in MgB₂.
