(Dated: November 23, 2018)

We present a method for density-functional modeling of metallic overlayers grown on metallic supports. It offers a tool to study nanostructures and combines the power of self-consistent pseudopotential calculations with the simplicity of a one-dimensional approach. The model is applied to Pb layers grown on the Cu(111) surface. More specifically, Pb is modeled as stabilized jellium and the Cu(111) substrate is represented by a one-dimensional pseudopotential that reproduces experimental positions of both the Cu Fermi level and the energy gap of the band structure projected along the (111) direction. The model is used to study the quantum well states in the Pb overlayer. Their analysis gives the strength of the electron confinement barriers at the interface and at the surface facing the vacuum. Our results and analysis support the interpretation of the quantum well state spectra measured by the scanning tunneling spectroscopy.

I. INTRODUCTION

The ability to manufacture desired nanostructures on solid surfaces by controlled growth or atomic manipulation techniques has increased enormously during the last decades.^{1,2} At the same time, spectroscopic methods to study different physical properties and phenomena of these structures have also experienced a huge development. In understanding and interpreting the ensuing experimental results rich of quantum phenomena, accurate theoretical and computational modeling plays a vital role.

A widely studied phenomenon is the growth of thin Pb films or extended Pb islands on solids, for example, on Si or Cu surfaces. The growth of Pb provides a laboratory to test the the so-called quantum size effects (QSE) arising due to the electron confinement perpendicular to the surface. The confinement results in discrete energy levels, the so-called quantum well states (QWS's). With the increasing film thickness new QWS's become occupied producing oscillations in the total energy, work function and other physical properties. The oscillations in the energy are the origin of the "magic" islands heights.^{3,4,5,6,7,8,9,10,11,12,13,14,15,16}

The most important feature characterizing an overlayer or a nanoisland is its height. However, measurements based on different physical processes may provide different values. The x-ray diffraction¹⁷ can be used to directly determine the number of atomic monolayers (ML) in thin films. The scanning tunneling microscope (STM)³ gives the thickness of finite nanoislands. In the helium atom scattering (HAS) the specular returning point of He atoms is measured.^{4,18} STM and HAS reflect the electron density profile of the surface.^{4,18} The scanning tunneling spectroscopy (STS) measures the QWS spectrum and the width of the quantum well confining the electrons is evaluated from it.¹⁹ In addition to the overlayer-vacuum surface profile, the QWS spectrum is sensitive also to properties of the substrate-overlayer interface. The information about the confining quantum well is important not only for the determination of the the film thickness but also for the understanding and controlling the so-called "electronic growth mode".

In this work we model thin Pb films growing in the [111] direction on the Cu(111) surface. We focus is on determining the surface and interface barriers of the confining quantum well and the ensuing QWS's. Pb/Cu(111)was recently studied by Otero et. al.¹⁹ They fitted the QWS spectra measured by STS by using the finitepotential-well model and unexpectedly found that actually the infinitely high potential barriers give a better fit than the more realistic finite barriers. One of our main aims is to resolve this dilemma. There are also recent STS measurements of QWS's in the Pb layers on Si(111).^{11,20,21} In these studies the overlayers are thinner and the QWS energy range is smaller than in the Pb/Cu(111) measurements by Otero et. al.¹⁹ The effective thickness of the Pb overlayer is then obtained by fitting the energy *differences* of the consecutive states. This is not very accurate and there are contradictory results for the thickness of the wetting layer, ranging from 1 ML 7,8,9 to 3 ML 10,11,20,21

There are several theoretical works based on the density functional theory (DFT) devoted to study QSE in thin films. First-principles atomapproaches^{22,23,24,25,26,27,28,29,30} istic or jellium models^{31,32,33,34,35} have been used. Usually, due to the high computational demand the substrate is not included, but the electronic structure is calculated for a slab describing the overlayer. The work by Hong et $al.^{36}$ for Pb/Si(111) is one exception. On the other hand, there are several simple analytic models for the confinement barriers,^{19,20,37} but *a priori* assumptions about the barrier type, its position or quantum numbers of the measured states can lead to an erroneous interpretation of the experiments. The simplifications made in the modeling hinder effectively the analysis of the experimental results.

In the present work we perform self-consistent electronic structure calculations by modeling the Cu(111) substrate with a one-dimensional (1D) pseudopotential and the Pb overlayer by stabilized jellium. The model includes the effect of the substrate-film boundary so that the penetration of the QWS into the substrate is realistically described. Our self-consistent results allow us to also study the above-mentioned simple analytical models and point out their deficiencies as well as the most important factors for the proper description of the electron confinement. This knowledge is specially important when using these models in analysing the STS results for completely covered substrates or for systems with wetting layers of unknown thicknesses.

In a previous publication¹³ we applied successfully the 1D-pseudopotential - stabilized-jellium model to gain physical insight into the "magic" heights of Pb islands on Cu(111) up to 23 ML of Pb.³ A pragmatic aim of the present paper is to document the construction of the unscreened 1D-pseudopotential and provide a simple parametrization which can be used in future studies, e.g. for different nanostructures on surfaces.

The rest of the paper is organized as follows: in Sec. II we report the practical steps for the construction of the Cu(111) pseudopotential. Then, we describe analytical models for the confinement barriers, whose reliability is analyzed by applying them to the results of the self-consistent calculations. Section III demonstrates the resulting self-consistent electronic structures for the Pb/Cu(111) system. The confinement barriers are analyzed and an improvement to the theory is introduced in order to acquire accuracy in their determination. Section IV contains the conclusions of the work. Atomic units (*i.e.*, $\hbar = e^2 = m = 1$ and distances measured in Bohr radius units $a_0 = 0.53$ Å) will be used throughout this work, unless otherwise specified.

II. THEORY

A. The model

The present calculations are performed in the framework of the DFT^{38} within the local density approximation $(LDA)^{39,40}$ and jellium-type models. Instead of finite Pb islands we consider infinitely-extended films on the Cu surface. This is justified because in the experiments considered the characteristic lateral dimension of the Pb islands is around $1000a_0$ [3,19] so that the lateral electron confinement effects are vanishingly small. Moreover, we assume the perfect translational invariance, i.e. a homogeneous free electron gas, along the surface (xy plane). We use a jellium model for the Pb overlayer and for the Cu substrate we construct a pseudopotential which varies only along the z direction perpendicular to the surface. Then the Kohn-Sham equations have to be solved numerically only in the z direction (1D problem). This enables the calculation of electron wavefunctions extending deep

into the Cu substrate and the modeling of systems having tens of Pb ML's.

The Kohn-Sham equations are discretized in a regular one-dimensional point mesh and solved with the Rayleigh quotient multigrid method,^{41,42} implemented in the real-space MIKA package⁴³ for electronic structure calculations. Hence, single-particle wave-functions are taken to be of the form

$$\Phi(\mathbf{r}) = \psi_n(z) e^{i\mathbf{k}_{\parallel} \cdot \mathbf{r}_{\parallel}},\tag{1}$$

where $\psi_n(z)$ is the wavefunction in the direction perpendicular to the surface, and plane waves are used for the surface parallel directions. The eigenenergies are given by

$$\epsilon_{nk_{\parallel}} = \epsilon_n + \frac{k_{\parallel}^2}{2},\tag{2}$$

where ϵ_n is the eigenvalue of the *n*-th perpendicular state $\psi_n(z)$. The eigenvalue ϵ_n , obtained self-consistently, is the bottom of the n-th subband. For finite and periodic systems in the *z* direction Dirichlet and periodic boundary conditions are used, respectively.

The effective or screened potential of the Kohn-Sham³⁸ equations in the z direction is written as

$$V_{\rm eff}(z) = \int \frac{n_{-}(z') - n_{+}(z')}{|z - z'|} dr' + V_{\rm xc}[n_{-}(z)] + V_{ps}(z),$$
(3)

where the first term on the right-hand side is the Hartree term $V_H(z)$, which includes the electron density $n_{-}(z)$ and the neutralizing rigid positive charge density $n_{+}(z)$. The second term gives the LDA exchange-correlation potential. The third term accounts for the pseudopotential that improves the simple jellium scheme. For the supported overlayer system $V_{ps}(z)$ has two contributions, one from the Pb overlayer and the other from the Cu(111)substrate. The free electron-like character of Pb at the Fermi level justifies the use of the stabilized jellium or averaged pseudopotential^{44,45} approach to model Pb. In practice, the jellium model allows us to simulate any Pb overlayer thickness.¹³ The Pb contribution to $V_{ps}(z)$ stabilizing the electron gas at the density corresponding to $r_s = 2.30a_0$ is a constant shift V_{stab} relative to the vacuum level and restricted in the region of the positive background charge. The stabilized Pb provides a proper work function so that the spilling of the electron density into the vacuum is well described. It also gives a proper value for the bottom of the valence electron band. This guarantees the correct Fermi wave length λ_F , which is of crucial importance for the properties related to the electron confinement.

For the Cu(111) substrate it is necessary to use a pseudopotential which accounts correctly for the width of the energy gap and its position with respect to the Fermi level. In this way, we obtain the correct confinement potential also at the Cu(111)-Pb interface. To obtain the 1D-pseudopotential we use the procedure described in

the following subsection. We start from a model potential and build an unscreened pseudopotential for Cu(111)in two steps.

B. Generation of the Cu(111) 1D-pseudopotential

1. Bulk pseudopotential $(1^{st} step)$

Chulkov *et al.*⁴⁶ proposed a fully screened 1D-modelpotential which varies only in the *z* direction perpendicular to the surface. The model potential is successfully used to study, for example, the dielectric response function and lifetimes of excited states.^{46,47,48} The crucial point here is the proper description of the energy band gap and work function. Moreover, the wave functions are correctly described not only outside the substrate, but also inside it. This is an important ingredient in the present application.

Because in this work we cover the Cu(111) surface with several ML's of Pb we skip the surface part of the 1D-pseudopotential. Nevertheless, it is also possible to build a pseudopotential which reproduces the surface and image states.⁴⁹ The bulk oscillating function of the 1Dmodel-potential⁴⁶ is

$$V_{model}(z) = A_{10} + A_1 \cos\left(\frac{2\pi}{d}z\right), \qquad \frac{-d}{2} < z < \frac{d}{2}$$
 (4)

where $d = 3.943a_0$ is the interlayer spacing in Cu in the [111] direction and A_{10} and A_1 are fitting parameters. Using periodic boundary conditions at $\pm d/2$ the Kohn-Sham equations are solved for the fixed $V_{eff}(z) =$ $V_{model}(z)$ potential. With the eigenfunctions obtained and with the experimental work function we calculate the electron density profile. Integrating over z we obtain the mean density with $r_s = 2.55a_0$. This value is close to the experimental $r_s = 2.67a_0$ for 4s electrons.

Once we have computed the density, it is straightforward to obtain the corresponding $V_{xc}(z)$ potential. It is more challenging to calculate the Hartree $V_H(z)$ term because in absence of vacuum we don't know the height of the dipole barrier, and therefore, where to fix the energy origin for the Hartree term inside the bulk. To solve the problem we fix provisionally the zero of the Hartree potential at the boundaries of the periodic cell. After adding a homogeneous neutralizing positive background of $r_s = 2.55a_0$, the Hartree potential can be evaluated. Finally, we can calculate from Eq. (3) the unscreened and periodic pseudopotential $V_{ps}(z)$ by subtracting from the effective potential the $V_H(z)$ and $V_{xc}(z)$ terms.

We have obtained, in this first step, the unscreened pseudopotential for periodic bulk calculations. Performing a self-consistent calculation for the bulk Cu(111) with this unscreened pseudopotential $V_{ps}(z)$ and a positive background density corresponding to $r_s = 2.55a_0$, we recover the experimental Fermi level with respect to the vacuum.

2. Pseudopotential for a semi-infinite system (2^{nd} step)

The unscreened 1D-pseudopotential from the first step is suitable for bulk calculations. But it cannot be used in slab calculations because the zero of the $V_H(z)$ potential was arbitrarily chosen in the previous step. We complete the pseudopotential for slab calculations in this second step.

We build a semi-infinite Cu(111) slab by repeating the pseudopotential for one ML of Cu. The slab is thick enough to avoid interaction between surfaces and finitesize effects in determining the band structure. Then, enough vacuum is added on both sides to annul boundary effects at the borders of the calculation volume. In the self-consistent calculation for this system the electron density spills out of Cu(111) to the vacuum giving rise to the dipole Coulomb barrier which places the Fermi level (and the whole band structure including the energy gap) at the incorrect position with respect to the vacuum level.

To correct the work function we shift the potential by a constant inside the Cu slab. Here we define the Cu(111) edge to be one half ML above the last atom plane. But the potential shift also changes the electron spilling into the vacuum and the dipole barrier. Thus, we have to find the potential shift iteratively so that the correct value for the work function is recovered. The value of the shift depends also on the possible smoothing (see below) of the positive background charge profile at the surface.

The 1D-pseudopotential vanishes suddenly at the Cu(111) surface, producing a discontinuity in the total potential. We have examined different ways to obtain a pseudopotential without the discontinuity. However, the final results obtained do not differ from the results obtained with the scheme described above and presented in this paper.

In summary, we have obtained a 1D-pseudopotential which with the positive background density of $r_s = 2.55a_0$ reproduces correctly the experimental Cu(111) work function and the [111]-projected band structure including the band gap. The method presented here for the Cu(111) pseudopotential generation is extensible to other substrates as well.

3. Analytic expression of the 1D-pseudopotential

The unscreened pseudopotential obtained can be fitted using the form of Eq. 4 for the screeneed model-potential. The result is, $A_{10} = -1.89 \ eV$ and $A_1 = 5.01 \ eV$. This pseudopotential is obtained with the positive charge background density corresponding to $r_s = 2.55a_0$ and a surface profile of the positive charge given by a Fermi-like distribution

$$\rho(z) = \frac{\rho_{Cu}}{e^{\frac{z-D_0}{\Delta z}} + 1}.$$
(5)

Above, D_0 is the surface edge position and $\Delta z = 0.09a_0$ accounts for the smoothing at the edge. The smoothing is used for numerical reasons.

C. Phase accumulation model for confinement barriers

We use the onedimesional-pseudopotential described above to simulate the Pb/Cu(111) system. In order to rationalize the results in a quantitative way, we employ simple analytical models reducing the information about the confinement barriers in few parameters. In particular, we are going to use the so-called phase accumulation model.³⁷ In this model a QWS in a confining potential fullfils the equation

$$2k_z D + \phi_{Cu(111)-Pb} + \phi_{Pb-vac} = 2\pi(n-1), \qquad (6)$$

where k_z is the wavevector corresponding to the QWS kinetic energy, D is the width of the potential well to model the Pb film, ϕ_{Pb-vac} and $\phi_{Cu(111)-Pb}$ are the phases of the eigenfunction accumulated at the vacuum surface and at the interface, respectively, and $n = 1, 2, 3, \ldots$ is the quantum number of the QWS. For an infinitely deep square potential well, the phase accumulated on each surface is $-\pi$. For softer potential barriers the value increases.

The phase shifts, usually calculated for model potentials given analytically, incorporate the physical features of the QWS's in a simple manner. An equivalent but more intuitive way is to apply the infinitely deep square potential well so that $\phi_{Pb-vac} = \phi_{Pb-Cu} = -\pi$, but using an effective width of $D' = D + \delta_{Cu(111)-Pb} + \delta_{Pb-vac}$. Then Eq. (6) gives

$$\delta_{Cu(111)-Pb} + \delta_{Pb-vac} = \frac{\pi n}{k_z} - D. \tag{7}$$

Here, $\delta_{Cu(111)-Pb}$ and δ_{Pb-vac} arise from the wavefunction penetration into the Cu(111) substrate and the spill out into the vacuum, respectively. The idea is that D'should give a reliable estimate of the actual thickness of the overlayer. Thus, as the phase shifts, also the effective well width depends on the QWS eigenenergy ε_n . It has been shown that the energy spectrum is very sensitive to the positions of the barriers and relatively insensitive to the barrier height.¹⁹ Therefore, a mean surface shift δ_0 can reproduce quite accurately the spectrum. According to Eqs. (6) and (7) the surface position shifts and phase shifts are related by

$$\delta = \frac{\phi + \pi}{2k_z}.\tag{8}$$

We consider below two analytical expressions for the surface-vacuum phase shift, the finite-potential-step and the image-potential models. The former gives the energy-dependent phase shift^{19,50}

$$\phi_{Pb-vac} = 2 \arctan\left(-\frac{k_{vac}}{k_z}\right) \tag{9}$$

FIG. 1: Electron density (solid line) and average positive background density (dashed line) for 4 ML's of Pb on the Cu(111). The origin z = 0 is at the Cu-Pb interface. The dotted curves show the electron densities of the free-standing Cu(111) and Pb slabs. The dash-dotted curve shows the charge transfer in the combined system relative to the freestanding Cu(111) and Pb slabs ($\Delta \rho = \rho_{Pb/Cu(111)} - \rho_{Cu(111)} - \rho_{Pb}$). The inset sketchs the symmetric geometry used in the calculations.

where $k_{vac} = \sqrt{2(-\varepsilon)}$ with the energy eigenvalue ε measured with respect to the vacuum level. This model has been used for the Cu-Pb interface barrier, too.¹⁹ The image-potential model gives the phase shift⁵¹

$$\phi_{Pb-vac} = \pi \sqrt{\frac{3.4 \text{ eV}}{-\varepsilon}}.$$
 (10)

The phase shift corresponding to the QWS wavefunction penetrating into the Cu(111) depends on the position of the QWS energy eigenvalue relative to the energy band gap. For example, the empiric formula⁵¹

$$\phi_{Cu(111)-Pb} = 2 \arcsin \sqrt{\frac{\varepsilon - \varepsilon_L}{\varepsilon_U - \varepsilon_L}} - \pi \qquad (11)$$

has been used. Above, ε_U and ε_L are the upper and lower edges of the band gap, respectively.

III. RESULTS AND DISCUSSION

A. Electronic structure

The main results of this paper are obtained with the pseudopotential generated in the previous section for the Cu(111) surface and the stabilized jellium model for the Pb overlayer. In the inset of Fig. 1 we sketch the geometry used in the calculations. In the middle there are 25 ML's of Cu and Pb overlayers corresponding up to 23 ML's (1 ML of Pb is 5.41 a_0) are attached symmetrically on both sides. Complementary calculations have been performed for unsupported Pb slabs, too.

FIG. 2: (a) Effective potential $V_{eff}(z)$ (solid line) and its components, the exchange-correlation potential $V_{xc}(z)$ (long-dashed line), Hartree term $V_H(z)$ (short-dashed line) and Pb stabilization potential V_{stab} (dotted line) for 4 ML's of Pb on the Cu(111) surface. The origin z = 0 is at the Cu-Pb interface and the energies are measured with respect to the vacuum level. The dash-dotted curve is the potential obtained by using the stabilized jellium model also for Cu. The straight horizontal line denotes the Fermi level ε_F . The vertical dotted lines represent the surfaces of the 4 ML Pb slab and the diamonds mark the position of atomic Cu planes. The shadowed regions distinguish the energy and space regions where localized QWS's can exist. (b) Energy eigenvalues as a function of the wavevector k_z . The open circles represent states extended over the whole system while the filled circles correspond to QWS's trapped in the Pb layer. The dotted parabola is the free-electron-model band in Pb plotted as a guide to the eye. The dark gray and ligh gray areas correspond to the Cu(111) energy gap and the potential well in Pb, respectively. The Cu and Pb free-electron-model Fermi wavevectors are marked for reference.

Fig. 1 shows the electron and positive background densities corresponding to the coverage of 4 ML's of Pb. We notice in the electron density in Pb six Friedel oscillations with the wavelength of about half Fermi wavelength. In the present case they are produced by the 6th QWS band, the bottom of which has dropped well below the Fermi level. The 7th QWS band is still unoccupied. This kind of well-developed Friedel oscillation pattern commensurate with the thickness of the overlayer is characteristic for the stable "closed shell" or "magic" overlayer systems. In Cu(111) the electron density oscillates strongly, according to Fig. 1, as a consequence of the oscillating pseudopotential.

Fig. 1 gives also the electron densities of the corresponding free-standing Cu(111) and Pb slabs as dotted curves. It is remarkable that the electron density moves from Pb towards Cu(111), indicating a possible increase in the effective width of the Pb slab. The charge transfer obtained when comparing the Pb/Cu(111) system with its free-standing counterparts ($\Delta \rho = \rho_{Pb/Cu(111)} - \rho_{Cu(111)} - \rho_{Pb}$) reveals charge accumulation at the interface. A small amount of charge (~ 5% of one Pb ML charge) is transferred from Pb to Cu in order to equilibrate their chemical potentials, ~ -4.1 eV and -4.94 eV for Pb and Cu, respectively. The charge transfer oscillates slightly as a function of the Pb slab thickness due to the oscillations in the Pb/Cu(111) Fermi level. These oscillations are in turn a consequence of the electron zconfinement in the Pb overlayer.

In Fig. 2(a) the effective potential V_{eff} and its components V_{xc} , V_H and V_{stab} are shown; the total pseudopotential V_{ps} is not plotted for clearness. The effective potential corresponding to the same system, but modeled with the stabilized jellium for Cu, is also drawn (dashdotted line), for comparison. Notice that it gives approximately the mean value of the Cu(111) pseudopotential. The dark gray shadowing gives the rough spatial extension where the localized QWS's can appear because of the Cu(111) energy gap. The light gray area marks the potential well between the vacuum barrier and the Pb-Cu interface barrier. This well is created because the potential in Pb is ~ 2 eV lower than the average Cu potential (notice the dash-dotted curve).

In Fig. 2(b) the eigenvalues are plotted as a function of the wavevector k_z . Actually, as will be explained below, it is not a straightforward task to assign a wavevector k_z to each state. Again, the dark gray area marks the position of the energy gap induced by the Cu(111) potential and the light gray area shows the lowest lying QWS's bound by the Pb-Cu interface barrier. The QWS's appearing in these energy regions are plotted with filled circles (Fig. 5 shows an example of the corresponding eigenfunctions (solid line)). The QWS's fall on the parabola (dotted line) which is the free-electron-model band for Pb. The states extending over the whole Cu-Pb system and forming a continuous band are plotted with open circles. The nearly parabolic band reflects the freeelectron character in our description of the Cu substrate. The QWS's in the lower, light gray area are supposed to have a minor relevance on the electronic properties of the system. In contrast, QWS's in the upper dark gray area play an important role, because increasing the Pb thickness lowers the QWS energy and they become occupied one by one.

The repeated occupation of new QWS's as a function of the overlayer thickness produces oscillations in all the electronic properties. In particular, oscillations in the energy give rise to Pb overlayers of especial stability. We studied recently these "magic" island heights using the present model for the electronic structures.¹³

As pointed out above, we divide the eigenstates into QWS's and bulk states. We use different methods to assign wavevectors k_z for these two groups of states. For bulk states, of minor importance in this study, we use the *particle-in-a-box* wavevector $k_z = \pi n/D$, where n is an integer and D the box width. On the other hand, QWS's are very localized in the Pb slab and we obtain their wavevectors from the confinement kinetic energy ϵ_k as $k_z = \sqrt{2\epsilon_k}$. ϵ_k is the energy difference between the QWS energy eigenvalue and the average potential value around the center of the Pb slab. The wavelengths can be measured also from the eigenfunctions and similar values are obtained. Below, the k_z vector turns out to be a relevant parameter when evaluating the phase shifts at the interfaces.

B. Determination of confinement barriers I

1. Comparison with the experiments

Scanning tunneling spectroscopy is capable of resolving energy levels of QWS's. Nevertheless, the interpretation of the experimental results is still difficult.^{7,19} The results obtained by our model provide a good tool to enlighten the problems encountered and to suggest a simple but realistic picture with relevant parameters.

Fig. 3 shows the calculated eigenvalues as a function of the number of Pb ML's. The comparison with the QWS energy levels measured by Otero *et al.*¹⁹ shows a good agreement for large coverage heights. Below 6 ML's the correspondence is a bit worse. This can be due to an inaccurate description of the Cu-Pb interface or due to the interaction with the Cu *d* electrons omitted in the calculations. The importance of these phenomena decreases as the number of ML's increases.

To explain the measured energy eigenvalues Otero *et al.*¹⁹ tried first the finite-square-potential-well model but the fit was not satisfactory. However, they obtained a very good agreement by using the infinite-square-potential-well model or by decreasing the width of the finite square well by $\sim 2.6a_0$. The fact that the infinite potential well produces much better results than the, in principle, more realistic finite potential well is coun-

FIG. 3: Energy eigenvalues of QWS's in the Pb overlayer on the Cu(111) surface as a function of the number Pb ML's. Open circles and filled diamonds give the calculated and experimental STS¹⁹ values, respectively. The dotted curves link points calculated with the infinite potential well model (See, Sec. II C) with the effective well width of $D' = D + 4.65a_0$. Dis the nominal width given by the number of Pb ML's. The energies are given with respect to the Fermi level.

terintuitive, because it has been proven for slabs,^{31,52} wires^{53,54} and clusters⁵⁵ that the real potential profiles are soft. In fact, it can be seen in Fig. 2a that the self-consistent potential is soft with an effective width increasing as a function of the QWS energy level. On the other hand, this effect seems not to be counterbalanced by the confining potential on the Cu-Pb interface. The QWS's penetrate inside the Cu(111) (see Fig. 5) and the electron density in Fig. 1 moves towards Cu. Nevertheless, a very good agreement with the experiments is obtained with both the infinite-square-potential-well model and soft self-consistent potentials. In addition, in Fig. 3 we show the eigenvalues (linked by dotted curves) obtained with the infinite-square-potential-well model but by using well widths increased by $4.65a_0$ in order to take into account the wavefunction spill-out. As can be seen, a good fit is obtained also in this way.

2. Calculation of the phase shifts

In order to clarify the reasons for these contradictions or dissimilar results, we use the phase-accumulation model and evaluate the phase shifts for the confinement barriers in our self-consistent calculations. We use the unsupported Pb slab to calculate the phase shift ϕ_{Pb-vac} and then we can evaluate the phase shift $\phi_{Cu(111)-Pb}$ in the Pb/Cu(111) system.

The procedure used is to choose a QWS with an energy just below the vacuum level and then to identify the corresponding quantum number n. After the wavevector k_z is calculated from the kinetic energy $\varepsilon = k_z^2/2$

as explained at the end of Section III A, the phase shift ϕ_{Pb-vac} is evaluated for the QWS energy level by Eq. (6). Increasing the slab thickness, the energy eigenvalue decreases and we calculate $\phi_{Pb-vac}(\varepsilon)$ as a function of the energy. The phase shift depends on the potential profile of the surface. Therefore we check that it remains unaltered for thicknesses over ~ 2 ML's. Once $\phi_{Pb-vac}(\varepsilon)$ has been calculated by using the unsupported Pb slab, the phase shift $\phi_{Cu(111)-Pb}(\varepsilon)$ can be evaluated in the same way using the results of the Pb/Cu(111) system. Similarly to the above procedure for the phase shifts, we also determine, according to Eq. (7), the shifts in the surface and interface positions $\delta_{Pb-vac}(\epsilon)$ and $\delta_{Cu(111)-Pb}(\epsilon)$, respectively.

The identification of the quantum number n is easy for states in free-standing Pb slabs. But it is difficult for the QWS's in the Pb/Cu(111) system because, in principle, it is not known how many states are hidden as resonances in the region of delocalized states in Cu (the white area between the gray ones in Fig. 2(b). Nevertheless, the local DOS integrated over the Pb overlayer reveals the number of the QWS resonances and, in addition, we have the possibility to plot the eigenfunctions in order to check the identification.

The dependences of the phase shifts on the energy eigenvalue are shown in Fig. 4. We notice that nearly in the whole energy range the phase shift at the Cu(111)-Pb interface is larger than that at the vacuum side. This means that the wavefunction penetration into Cu(111) is larger than the spill out into the vacuum. The behaviour of the phase shift $\phi_{Pb-vac}(\epsilon)$ can be compared with that obtained in the three-dimensional DFT calculations with more realistic atomic pseudopotentials. For example, the results by Wei and Chou²² are in a qualitative agreement with the preset ones.

The phase shifts of the image-potential model, Eq. (10), reproduce quite well our results with the exception of the energies close to the vacuum level. This is due to the exponential decay of the DFT potential into the vacuum. The empirical Eq. (11) gives good results at the Cu-Pb interface if one corrects for the known downward shift of π .⁵⁶ The finite-square-potential-well model does not produce phase shifts in agreement with the self-consistent results.

We plot in Fig. 4(b) the shifts of the barriers in the infinite-square-potential-well model according to Eq. (7) as a function of the energy eigenvalue. In the energy window from -1 to 3 eV accessible in the STS measurements the effective width increases more at the Cu(111)-Pb interface than at the Pb-vacuum surface. The shift of the effective Pb-vacuum barrier is in agreement with the jellium-model calculations by Stratton⁵² who obtained the average shift of 1.41a₀ between the bottom of the potential well (at -9.5 eV) and the Fermi level.

Combining the results of Fig. 4 and Eqs. (6) or (7), the eigenvalues in Fig. 3 are reproduced. (The energy eigenvalues have to be shifted downwards by the width 9.5 eV of the occupied energy band.) A good qualitative

FIG. 4: (a) Cu(111)-Pb and Pb-vacuum phase shifts as a function of the QWS eigenenergy given with respect to the Fermi level. The solid curves give the results of our DFT calculations. The dashed curves denote the values obtained by using Eqs. (10) and (11) for the Pb-vacuum and Cu(111)-Pb phase shifts, respectively (π is added to Eq. (11)). The dotted curve corresponds to the finite-potential-step model for the Pb-vacuum barrier. (b) Shifts in the effective Cu(111)-Pb interface and Pb surface positions are given by solid and dashed curves, respectively.

behaviour is obtained simply by using the mean effective width D' which is the ideal width D increased by $\sim 4.65a_0$. The dotted curves in Fig. 3 link the eigenenergies calculated in this way.

We compare in Fig. 5 our self-consistent DFT calculation for the Pb/Cu(111) system with two simple model calculations. There are 5 ML's of Pb on the Cu(111) surface and we plot the electron density of the QWS at $\varepsilon = 0.53$ eV (solid line). The corresponding state in a free-standing Pb slab (dashed line) is obtained by shifting the left Pb-vacuum boundary by $0.75a_0$ to the left in order to mimic the larger penetration of the wavefunc-

FIG. 5: Electron density of a QWS in the 5 ML thick Pb overlayer on Cu(111). The solid curve results from the self-consistent DFT calculation for the Pb/Cu(111) system. The dashed and dash-dotted curves are obtained using the free-standing Pb slab and the infinite-square-potential-well model, respectively. The gray region denotes the Pb overlayer on Cu(111). For the details, see the text.

tions into Cu(111) than into vacuum. The value of $0.75a_0$ reproduces the correct infinite-barrier shift in Fig. 4(b). The eigenenergy of this Pb slab state is also 0.53 eV. On the right surface, of course, both wavefunctions overlap and at the left surface the slab wavefunction tries to mimic, without oscillations, the decay of the wavefunction in the Pb/Cu(111) system. The corresponding state calculated using the infinite-square-potential-well model with the appropriate shifts of the barriers $(1.66a_0)$ and $2.37a_0$ from Fig. 4(b)) is also given in Fig. 5 (dashdotted line). Note that this simple model gives the correct energy eigenvalue and describes well the wavefunction inside Pb but it cannot account for the decay into the Cu substrate. In conclusion, the two simple models reproduce quite well the eigenfunctions inside Pb and at the Pb-vacuum barrier, but not beyond the Cu(111)-Pb interface. In order to describe properties related to the penetration of the wavefunctions into the substrate, the slab and infinite-square-potential-well models are inadequate.

3. Importance of quantum numbers

The model based on the phase shifts or on the effective width increase of the infinite potential well reproduces the eigenvalues and eigenfunctions of the self-consistent calculation. Because the self-consistently calculated eigenvalues agree with the experimental ones,¹⁹ the latter can be fitted with $\delta \approx 4a_0$. Nevertheless, Otero *et al.*¹⁹ obtain a good agreement with $\delta = 0$.

To explain the contradiction we have compared the infinite-square-potential-well energy spectrum (Eq. (7) obtained with $\delta = 0$) and our model results correspond-

ing to $\delta \neq 0$. In the latter the quantum number n for the eigenstates with the nearly constant eigenenergy of 0.65eV are $n = 4, 7, 10, \dots$ for $2, 4, 6, \dots$ ML's of Pb, respectively. Actually, this is in agreement with the pseudopotential calculations for free-standing Pb slabs. 22 But $\delta = 0$ gives the corresponding quantum numbers as $n = 3, 6, 9, \ldots$ *i.e.*, they are one unit smaller than the correct set. This explains why both models reproduce approximately the same experimental energy spectrum. The wavelength of the states $n = 3, 6, 9, \ldots$ at 0.65 eV in the infinite potential well is $\lambda_{0.65} = 7.2a_0$. When we increase the width of the well by $\lambda_{0.65}/2$ the states $n = 4, 7, 10, \ldots$ lie exactly at the same energy. This does not hold for energies far from 0.65eV and the eigenenergy spectra become remarkably different. Nevertheless, in the narrow energy window from -1 to 3 eV scanned in experiments, the energy spectra of both models are very similar and fit quite well the experimental results. As a matter of fact, an even better fit of experiments seems to be obtained by increasing the width of the potential well by $\lambda_{0.65}$ and using states with quantum numbers n two units larger than in the original infinite-square-potentialwell model.

In conclusion, the energy spectra can be fitted with several different thickness and quantum numbers. The danger is that other properties such as the wavefunctions or "magic" heights are wrongly determined. For example, the correct determination of the physical parameters reveals crucial in the description of the envelope function which plays a key role in determining the energetics of the quantum well states⁵⁷ or the magnetic coupling in multilayer structures.⁵⁸

C. Determination of confinement barriers II

1. Calculation of δ from energy differences

The disadvantage of the previous method for determining the positions of the confining barriers is the necessity to measure a large number of QWS eigenenergies in order to label correctly the quantum states. However, there exists methods in which the knowlegde of the quantum number n is not needed.^{11,20,21,22} We now elaborate this kind of methods.

From the energy difference Δ_n between two consecutive states, one can obtain an effective thickness $D' = D + \delta_0$ of the infinite potential well as

$$\Delta_n = \varepsilon_{n+1} - \varepsilon_n = \frac{\pi^2 (2n+1)}{2(D+\delta_0)^2} = \frac{k_0 \pi}{D+\delta_0}.$$
 (12)

Above, D is the thickness of the positive background density of the overlayer slab or, in the case of experiments, the measured thickness. $k_0 = \frac{\pi(n+0.5)}{D+\delta_0}$ is a wavevector depending on n and D'. As before, δ_0 is the difference between the measured nominal value and the effective one confining the electrons. The latter takes into account, e.g., the effect of the electron spill out into the

FIG. 6: Effective thickness $k_0 \pi \Delta_n^{-1}$ calculated from the theoretical QWS energies in Fig. 3 (energy window from -1 to 3.5 eV) as a function of the Pb jellium slab thickness. The diamonds and dashed line correspond to the data and fit according to Eq. (13). The circles and the solid straight line are the data and the fit according to Eq. (15). The crosses are the exact effective thickness calculated from $D' = \pi n/\sqrt{2\varepsilon_n}$. Data for 23 ML's are used in the fitting, but only data for 11 ML's are plotted for clarity.

vacuum or into the substrate, the unknown thickness of the wetting layer, and effects due to stress or relaxation at the boundaries.

We consider QWS's in overlayers of different thickness and within a given window, e.g. the QWS's shown in Fig. 3. We write Eq. (12) as

$$\Delta_n^{-1} = \frac{(D + \delta_0)}{k_0 \pi}.$$
 (13)

Then, by plotting Δ_n^{-1} as a function of D and by fitting a straight line to the data, the slope gives k_0 averaged over the energy window in question. For example, the theoretical data of Fig. 3 gives $k_0 = 0.88a_0^{-1}$ which corresponds to the kinetic energy of 10.5eV, i.e. an energy $\sim 1 \text{ eV}$ above the Fermi level.

The original theoretical data and the fit are shown in Fig. 6 by the diamond markers and by the dashed straight line, respectively. We plot $D' = k_0 \pi \Delta_n^{-1}$, instead of Δ_n^{-1} , as a function of D. This is because we want to include the exact values $D' = \pi n / \sqrt{2\varepsilon_n}$ and the results of Eq. (15) (see below). The intersection of the dashed straight line with the vertical axis gives $\delta_0 = 14a_0$. This value is much larger than the value obtained for the total shift of the potential barriers in Section III B. Namely, at the energy of 1eV above the Fermi level we obtain from Fig. 4(b) that $\delta_0 = 4.5a_0$.

The method described above (Eq. (13)) has been used to determine the number of Pb wetting layers in the STS. Our finding that the method overestimates the distance between the confinement barriers may explain the large

FIG. 7: Energy eigenvalues (bottoms of subbands) of a freestanding 8 ML thick Pb slab as a function of the quantum number n. The open circles and the filled diamonds give the results of the stabilized-jellium and infinite-potential-well models, respectively. In the latter, the width of the well corresponds to 8 ML widened by 4.5 a_0 in order to take into account the electron spill out. The vacuum level defines the zero energy level. The inset shows the energy differences between the consecutive states as a function of the energy. The energy range of the QWS's in the Pb/Cu(111) system is given.

 $values^{11,20,21,22}$ obtained by this scheme in comparison with other experiments.^{7,8,9} The reason for this disagreement is the basic fact that Eqs. (12) and (13) correspond to the infinite potential well, whereas a finite potential well is closer to reality. The infinite-square-potential-well model with the shifts δ_0 of the confining barriers reproduces quite accurately the energy spectrum as is demonstrated in Fig. 7. The figure shows that the infinite potential well with the thickness of $8ML+4.5a_0$ mimics the energy spectrum of a 8 ML unsupported Pb jellium slab. But the reasoning to the opposite direction, the determination of the δ_0 value from the real energy spectrum cannot be done using the scheme. The explanation is that the energy eigenvalue differences Δ_n between the consecutive states behave differently in the infinitesquare-potential-well and in real systems. The inset of Fig. 7 shows that the infinite potential well results in a monotonically increasing Δ_n whereas in the more realistic stabilized-jellium model Δ_n decreases close to the vacuum level. The wrong trend in the infinite-squarepotential-well model is compensated by the erroneously large effective width of the Pb slab or overlayer obtained by applying Eq. (13). In the next subsections we suggest a method purified from this effect.

2. Corrected formula for the calculation of δ_0

The option we choose to correct the overestimation inherent in Eq. (13) is to introduce the effect of the finite potential barrier. This can be done by assuming that the surface shift is energy-dependent as $\delta = \delta_0 + \delta(\varepsilon)$. Here, δ_0 is the mean value we want to determine. Our aim is to obtain information about the electron confinement strength through the δ_0 parameter, which is energyindependent but it is reproduces satisfactorily the energy spectrum (see Fig. 7). Nevertheless, it is necessary to use the energy-dependent $\delta(\varepsilon)$ function to obtain relevant δ_0 values.

The energy difference between the successive states can be obtained to the first order as $\Delta_n = \frac{d\varepsilon}{dn}$ (*n* increases by unity). The energy derivative for a given thickness D' is

$$\frac{\mathrm{d}\varepsilon}{\mathrm{d}n} = \frac{\pi^2 n}{D'^2} - \frac{\pi^2 n^2}{D'^3} \dot{\delta}(\varepsilon) \frac{\mathrm{d}\varepsilon}{\mathrm{d}n} \tag{14}$$

where $\delta(\varepsilon)$ is the energy derivative of the surface shift and it depends on energy. This equation has to be evaluated for a given *n*. For the infinitely deep potential well $\dot{\delta} = 0$ and we do not recover the exact result of Eq. (12). This deficit can be corrected by evaluating the right-hand side of Eq. (14) at (n+1/2). The corresponding $\dot{\delta}$ is also evaluated at $(\varepsilon_{n+1} + \varepsilon_n)/2$ using the self-consistent δ values shown in Fig. (4b). Then, rearranging the terms of Eq. (14) we obtain the corrected formula for the thickness as

$$\pi k_0 \Delta_n^{-1} - k_0^2 \,\dot{\delta} = D' = D + \delta. \tag{15}$$

Here, it is accurate enough to use the k_0 obtained previously with Eq. (12). Omitting the dependence of δ on energy on the right hand side of Eq. (15), i.e. $\delta = \delta_0$, we can calculate the value of δ_0 by fitting a straight line for D' as a function of D.

The circles and the solid straight line in Fig. 6 give the D' values and the fit, respectively, corresponding to Eq. (15). The new mean value $\delta_0 = 5.4a_0$ is consistent with the electron spill out shown in Fig. (4b) and it is much better than the value of $14a_0$ obtained with the uncorrected formula (13). Namely, the exact values $D' = \pi n/\sqrt{2\varepsilon_n}$ (shown as crosses in Fig. 4) give $\delta_0 = 4.85a_0$.

3. Analytic models for the $k_0^2 \dot{\delta}$ correction

In order to apply the corrected scheme of the previous subsection the energy-dependent derivative $\dot{\delta}(\varepsilon)$ has to be known. We study now the reliability of different analytical models in its estimation. These models allow us to extend the previous analysis to other substrates or overlayers without doing self-consistent electronic structure calculations.

The finite-square-potential-well model does not provide a correction large enough, because the potential is not a continuous function of energy. The $\dot{\delta}$ values are too small (see Fig. 4(a)). The image-potential model (Eq. (10)) and the empiric phase shifts (Eq. (11)) provides results in a much better agreement with experiments. We want to emphasize that even if the analytical phase

FIG. 8: Derivative $\dot{\delta}(\varepsilon)$ of the effective thickness with respect to the energy according to different models. The solid and dash-dotted curves give the self-consistent results for the interface and surface components, respectively. The dotted curve shows the analytical result for the surface component obtained by using the image potential model of Eq. (10). The dash-dotted curve gives the result for the interface component obtained by using the empirical formula (11). The energy origin is at the Fermi level.

shifts may not produce the same δ_0 values as the selfconsistent calculations (for example, due to the fact that the phase shift is determined with the module of 2π) they reproduce reasonably well the energy derivative $\dot{\delta}$ needed in the correction in Eq. (15).

Fig. 8 shows the derivatives δ from the self-consistent calculation and from the analytical models of Sec. II C. The agreement is quite good, even if the derivatives of the self-consistent calculation are generally smaller. Comparing self-consistent and analythical curves we notice that small differences in the phases (Fig. (4)) produce big differences in Fig. 8. As a matter of fact, at energies close to the vacuum the image-potential results could be more relevant than the self-consistent DFT results, which are affected by the exponential decay of the DFT potential. Because according to Fig. 8 the correction is large at energies close to the vacuum level and also close to the bottom of the projected energy gap of the substrate, we recommend the use of QWS's at intermediate energies when determining the overlayer thickness.

Table I shows a collection of δ_0 values obtained for several systems using different approximations. In addition to our theoretical results for the Pb/Cu(111) and the free-standing Pb slab systems we analyze our similar results for Na/Cu(111) and the experimental QWS spectrum of Pb/Cu(111) [19]. The "exact δ_0 " values are obtained by fitting a straight line through the exact results $D' = \pi n/\sqrt{2\varepsilon_n}$. In general, the uncorrected Eq. (13) gives for the Pb systems δ_0 values nearly three times larger than the exact one. In contrast, the corrected value

TABLE I: δ_0 's (in Bohr radii a_0) determining the effective widths of the infinite potential wells fitting the QWS energy spectra. The values are calculated from different theoretical and experimental spectra by using the uncorrected sheme of Eq. (13) as well as the scheme of Eq. (15)) with the numerical correction obtained from the self-consistently calculated results or from the analytical image-potential and empiric formulae. The exact values are obtained by employing the equation $D' = \pi n/\sqrt{2\varepsilon_n}$ with the known *n* quantum numbers. The maximum overlayer thickness (in ML's) used in fitting are given in the second column. The numbers in parenthesis give the linear regression errors. The QWS of the DFT calculations used in fitting span the energy range from ~ 1eV below Fermi level, i.e. from the bottom of the Cu(111) band gap, to ~ 1eV below vacuum level (for Pb/Cu(111) corresponds to the experimentaly measured energy range of QWS's).

System	Up to	δ_0 from Eq. (13) uncorrected	δ_0 from Eq. (15) numerical correction	δ_0 from Eq. (15) analytical correction	Exact δ_0
Pb/Cu(111)	$23 \mathrm{ML}$	12(1)	5(2)	3(2)	4.7(0.1)
Pb/Cu(111)	$10 \mathrm{ML}$	13(1)	6(1)	4(2)	4.8(0.3)
Experiments ¹⁹	$24 \mathrm{ML}$	15(5)	7(5)	5(5)	4.0(0.2)
Na/Cu(111)	$20 \mathrm{ML}$	7(3)	1(3)	3(4)	1.2(0.3)

offers a sub-monolayer accuracy.

For the Na/Cu(111) system the difference between the corrected and uncorrected δ_0 is large as well. Although the wavelength of Na is larger than for Pb, δ_0 does not scale with it. The deeper potential of Cu(111) than the Na potential (the opposite to the Pb/Cu(111) system) shifts the barrier inside the Na, i.e. the value of $\delta_{Cu(111)-Na}$ is negative. This explains the small value of δ_0 .

It is noticeable that applying Eq. (15) with the numerical and the analytical corrections to the experimental results of ref. [19] we obtain $\delta_0 = 7.3a_0$ and $4.7a_0$, respectively. These values are much smaller than the uncorrected value of $14.9a_0$. When we compare with the exact value of $4.0a_0$, which is obtained by identifying first the *n* quantum numbers. The linear regression error is anyway substantial. In addition to the errors due to our first-order approximation in Eq. (14), the experimental dispersion in the QWS spectrum cause uncertainty. In general, for self-consistent calculations the numerical correction provides better determination of δ_0 compared to the analytical one. But in the case of the experimental data the analytical correction is better.

When analyzing experiments, the δ_0 value obtained by the corrected scheme of Eq. (15) can be used as an initial parameter to determine the *n* quantum number. Then, employing the exact equation to fit the energy spectrum, improved results are obtained.

IV. CONCLUSIONS

We have performed self-consistent DFT calculations to study the confinement barriers of electrons in Pb islands grown on the Cu(111) substrate. Calculations have been done for free-standing Pb slabs and Pb slabs on Cu(111). Pb was described by stabilized jellium and the Cu(111) substrate by a 1D-pseudopotential. The model reproduces the most important physical properties and gives results in a good agreement with experiments.

The energies and wavefunctions of the quantum well states in the Pb slabs characterize the confinement barriers at the Pb-vacuum surface and at the Cu(111)-Pb interface. We have analyzed these states by using the phase accumulation model and by determining effective widths of infinite potential wells reproducing the energies. The Pb-vacuum phase shift is in a good agreement with more realistic pseudopotential calculations. The Cu(111)-Pb phase shift or the effective width of the potential well accounts for the confining strength of the Cu(111) energy gap. This strength is weaker than that of the Pb-vacuum barrier.

The information provided by our calculations and analysis allows to improve the interpretation of QWS spectra measured by scanning tunneling spectroscopy. More specifically, we have shown that a formula commonly used in the literature results easily in the overestimation of the effective width of the infinite potential well. We have offered an alternative expression to correct that deficiency, specially important for electronic high density (small λ_F) metals. The obtained results can be used to estimate the width of the potential well and to determine the quantum numbers for a more accurate analysis of the confinement barriers.

Finally, the 1D-pseudopotential scheme provides a method for future studies of nanostructures on solid surfaces. Despite this work is focused on STS experiments and Pb/Cu(111) system, our results can be qualitatively applied to metallic nanoislands on semiconducting substrates, e.g. Pb or Ag on Si, as well as to photoemission experiments.
