The 4D compact U(1) lattice gauge theory (LGT) in the confinement phase is studied with the multi-level algorithm. The static potential, force and flux-tube profile between two static charges are precisely measured from correlation functions involving the Polyakov loop. Universality of the coefficient of the 1/r correction to the static potential, known as the Lüscher term, and the transversal width of the flux-tube profile are investigated.

1. Introduction

If the confining gauge theory is related to an effective bosonic string theory, the long range behavior of the potential between static charges separated by distance r is expected to have the form:

$$V(r) = \sigma r + \mu + \frac{\gamma}{r} + O(\frac{1}{r^2}). \tag{1}$$

Here σ is the string tension and μ denotes a constant. The third term is known as the Lüscher term [1], where the coefficient, $\gamma = -\pi (d-2)/24$ with space-time dimension d, is considered to be universal. The effective bosonic string theory also predicts that the width of the field energy distribution of the flux tube diverges logarithmically as $r \to \infty$ [2]. Recent Monte-Carlo simulations of various LGTs support Eq. (1) with high accuracy: the confinement phase of \mathbb{Z}_2 LGT [3], SU(2) LGT [4] and SU(3) LGT [5].

In this report we investigate the long range properties of compact U(1) LGT in the confinement phase. From the Polyakov loop correlation function (PLCF), we extract the potential and force to see whether this theory also supports the presence of the universal correction to the static potential. We then measure the profile of the flux tube induced by the PLCF, and see the behavior of its width as a function of r. However, due to its strong coupling nature, the Monte Carlo simulation of compact U(1) LTG is numerically difficult, when its long range properties are of interest. To obtain reliable signals, we apply here the multilevel algorithm proposed by Lüscher and Weisz originally for SU(3) LGT [6], which helps to reduce statistical errors exponentially.

2. Numerical procedures

We adopt the terminology of Ref. [6]. To measure the PLCF, $\langle P^*P(R)\rangle$, where R = r/a, we take second-level averages of the two-link correlators $\mathbb{T}(m; R; i) = U_4^*(m)U_4(m + R \ \hat{i})$ with $m = (m_s, m_t)$ as

$$\mathbb{T}^{(2)}(m_s, \bar{m}_t; R; i) = [\mathbb{T}(m; R; i)\mathbb{T}(m + \hat{4}; R; i)], (2)$$

which is achieved by updating link variables except for the spatial links at $\bar{m}_t = 1, 3, \ldots, N_t - 1$. N_t is the timelike extent of the lattice volume. i = 1, 2, 3 denote directions between the two charges. We call this procedure the *internal update*. We repeat the internal update until reasonably stable values for $\mathbb{T}^{(2)}$ are obtained. Then the PLCF at a spatial site m_s is constructed as

$$P^*P(m_s; R; i) = \operatorname{Re} \mathbb{T}^{(2)}(m_s, 1; R; i) \\ \times \mathbb{T}^{(2)}(m_s, 3; R; i) \cdots \mathbb{T}^{(2)}(m_s, N_t - 1; R; i).$$
(3)

The average with respect to m_s and i provides $[P^*P(R)]_{i_c}$. The desired expectation value is the average of $[P^*P(R)]_{i_c}$ for $i_c = 1, 2, \ldots, N_c$. In the actual measurements, we have also applied the multi-hit technique to the timelike link variables for $R \geq 2$ before constructing \mathbb{T} . The static potential and the corresponding force are taken as (neglecting terms of $O(e^{-\Delta E N_t})$)

$$aV(R) = -\frac{1}{N_t} \ln \langle P^* P(R) \rangle , \qquad (4)$$

^{*}Talk presented by Y. Koma.

$$a^2 F(\bar{R}) = aV(R) - aV(R-1)$$
, (5)

where $\bar{R} = R - 1/2 + O(a)$.

In order to measure the flux-tube profile, one needs to compute a correlation function of the type

$$\langle \mathcal{O}(n) \rangle_j = \frac{\langle P^* P \mathcal{O}(n) \rangle_0}{\langle P^* P \rangle_0} - \langle \mathcal{O} \rangle_0 , \qquad (6)$$

where \mathcal{O} is a local operator, $\langle \cdots \rangle_j$ denotes an average in the vacuum with the PLCF, and $\langle \cdots \rangle_0$ an average in the vacuum without such a source. To measure $\langle P^*P\mathcal{O}\rangle_0$ on the mid-plane between two static charges, we parameterize the position of the local operator n as $n = (n_i = m_i + R/2, n_j = m_j + x, n_k = m_k + y, n_t = m_t)$ and take the average of the two-link-local-operator correlator

$$\mathbb{TO}^{(2)}(m_s, \bar{m}_t; n; R; i) = [\mathbb{T}(m; R; i)\mathbb{O}(m + \hat{4}; n; R; i)].$$
(7)

with $\mathbb{O}(m; n; R; i) = U_4^*(m)U_4(m + R\hat{i})\mathcal{O}(n)$ in addition to $\mathbb{T}^{(2)}$. Combining $\mathbb{TO}^{(2)}$ and $\mathbb{T}^{(2)}$, we obtain $\langle P^*P\mathcal{O}\rangle_0$.

As local operators, we have used $\mathcal{O}_E(n) = i\bar{\theta}_{\mu\nu}(n)$ for the electric field, and $\mathcal{O}_k(n) = 2\pi i k_{\mu}(n)$ for the monopole current as defined in Ref. [7]. Note that the second term of Eq. (6) vanishes for these operators since \mathcal{O}_E and \mathcal{O}_k are parity odd.

3. Numerical results

We generate a sequence of independent gauge field configurations, by using the Wilson gauge action of compact U(1) LGT on a 16⁴ lattice at $\beta = 0.98, 0.99, 1.00, 1.005$ and 1.01. For the first three β values, the configuration has been generated after 500 thermalization sweeps, and they were separated by 100 sweeps, where one Monte Carlo update has been achieved by 1HB/3OR. For $\beta = 1.005$ and 1.01 the thermalization sweeps have been taken 1000 and 3000, respectively, with 1HB/5OR Monte Carlo update.

For the static potential and force, we have used $N_c = 1050, 1250, 2050, 2400$ and 3200 configurations, respectively. The internal updates have been taken as $N_{\text{iupd}} = 10000, 8000, 5000, 3000$

Figure 1. The static potential as a function of r/r_0 . The constant μ is subtracted by using the fit result of Eq. (1), neglecting $O(1/r^2)$ corrections.

and 1000. These numbers are optimized to measure the PLCF up to R = 6 with < 10 % errors, where the PLCF themselves take values from 10^{-3} to 10^{-17} . From the force, we have introduced a scale based on Sommer's relation $r_0^2 F(r_0) = 1.65$. Lattice spacings in units of r_0 are found to be $a/r_0 = 0.470, 0.422, 0.353, 0.305$ and 0.217, respectively.

In Figs. 1 and 2, we show the static potential and force from all β values. They show good scaling behaviors. We also plot the theoretical prediction for the force based on Eq. (1) in Fig. 2. We find that the long distance behavior is welldescribed by the function, $F = dV/dr = \sigma - \gamma/r^2$ with $\sigma r_0^2 = 1.65 - \gamma = 1.39$, which contains no fitting parameter. This supports the universal-

ity of γ/r correction to the static potential. Surprisingly, another feature in common with non-Abelian gauge theories is that this function also fits the data down to relatively short distance to $r/r_0 \sim 0.3$. For this, there is as yet no explanation.

We have measured flux-tube profiles with lengths R = 3 to 6 at $\beta = 0.99$ to 1.01 and R = 3 to 5 at $\beta = 0.98$. We have applied $N_{\rm iupd} = 200 \sim 8000$ depending on R and β . The number of configurations are $N_c = 300$ for all β values. As an example, we show the profiles of the electric field and monopole current for R = 5 at $\beta = 0.98$ in Fig. 3, which is the longest flux tube in these measurements: $r/r_0 = 2.35$. Here we have taken the cylindrical average: $\rho = \sqrt{x^2 + y^2}$ and $\varphi = \tan^{-1}(y/x)$. As shown in this figure, we have obtained very clean signals, however, rotational invariance for the monopole current profile seems not good due to the relatively large lattice spacing at $\beta = 0.98$. For larger β , we obtained smoother curves.

There are several definitions of the width of the flux tube. Here, we have investigated this in terms of the peak radius of the monopole current profile, ρ_{eff} . In order to find ρ_{eff} we have interpolated the on-axis data with a smooth curve. The result as a function of r/r_0 is shown in Fig. 4, where we have picked only the data with R = 5for all β values; ρ_{eff} seems to grow as increasing r. However, we make no statement on the

Figure 4. The peak radius of the monopole current profile as a function of r/r_0 .

behavior whether the width diverges as $r \to \infty$. Also, since the rotational invariance is not good for small β values, we have to check the validity of the smooth interpolation carefully. Further detailed analyses are in progress [8].
