

An algebraic geometry approach to nonlinear parametric optimization in control

Ioannis A. Fotiou*, Philipp Rostalski*, Bernd Sturmfels† and Manfred Morari*

Abstract— We present a method for nonlinear parametric optimization based on algebraic geometry. The problem to be studied, which arises in optimal control, is to minimize a polynomial function with parameters subject to semialgebraic constraints. The method uses Gröbner bases computation in conjunction with the eigenvalue method for solving systems of polynomial equations. In this way, certain companion matrices are constructed off-line. Then, given the parameter value, an on-line algorithm is used to efficiently obtain the optimizer of the original optimization problem in real time.

I. INTRODUCTION

Optimal control is a very active area of research with broad industrial applications [1]. It is among the few control methodologies providing a systematic way to perform nonlinear control synthesis that handles also system constraints. To a great extent, it is thanks to this capability of dealing with constraints that model predictive control (MPC) has proven to be very successful in practice [2], [3].

Model predictive control uses optimization on-line to obtain the solution of the optimal control problem in real time. This method has been proven most effective for applications. Typically, the optimal control problem can be formulated into a discrete time mathematical program, whose solution yields a sequence of control moves. Out of these control moves only the first is applied, according to the receding horizon control (RHC) scheme.

The optimal control problem is formulated as a mathematical program, which can be a linear program (LP), a quadratic program (QP) or a general nonlinear program (NLP). For hybrid systems, the corresponding mathematical programs can be mixed integer programs - MILPs, MIQPs or MINLPs [4]. The class of the optimization problem depends on the objective function and the class of systems one wants to derive an optimal controller for.

Technology and cost factors, however, make the implementation of receding horizon control difficult if not, in some cases, impossible. To circumvent these issues, the solution of the optimal control problem is computed off-line, by solving the corresponding mathematical program parametrically [5]. That is, we compute the explicit formula giving the solution of the program (control inputs) as a function of the problem parameters (measured state). The solution then is efficiently implemented on-line as a lookup table.

In the present work, we extend the concept of the explicit solution to the class of nonlinear polynomial systems with polynomial cost function. By polynomial systems we mean those systems, whose state update equation is given by a polynomial vector field. For this class of systems, the resulting mathematical program is a nonlinear (polynomial) parametric optimization problem.

While the *explicit solution* is not generally possible in the nonlinear case, we stress the fact that a *partial precomputation* of the optimal control law is still feasible using algebraic techniques [6]. In this paper, we use the eigenvalue method [7] in conjunction with Gröbner bases computation to perform nonlinear parametric optimization of polynomial functions subject to polynomial constraints.

II. PARAMETRIC OPTIMIZATION

Let $u \in \mathbb{R}^m$ be the decision-variable vector and $x \in \mathbb{R}^n$ be the parameter vector. The class of optimization problems that this paper deals with can generally assume the following form:

$$\min_u J(u, x) \quad \text{s.t.} \quad g(u, x) \leq 0, \quad (1)$$

where $J(u, x) \in \mathbb{R}[x_1, \dots, x_n, u_1, \dots, u_m]$ is the objective function and $g \in \mathbb{R}[x_1, \dots, x_n, u_1, \dots, u_m]^q$ is a vector polynomial function representing the constraints of the problem. By parametric optimization, we mean minimizing the function $J(u, x)$ with respect to u for any given value of the parameter $x \in \mathcal{X} \subseteq \mathbb{R}^n$, where \mathcal{X} is the set of admissible parameters. Therefore, the polynomial parametric optimization problem is finding a computational procedure for evaluating the maps

$$\begin{aligned} u^*(x) : \mathbb{R}^n &\longrightarrow \mathbb{R}^m \\ x &\longmapsto u^* \\ J^*(x) : \mathbb{R}^n &\longrightarrow \mathbb{R} \\ x &\longmapsto J^*, \end{aligned} \quad (2)$$

where

$$\begin{aligned} u^* &= \operatorname{arg\,min}_u J(u, x) \\ J^* &= \min_u J(u, x). \end{aligned} \quad (3)$$

For the sake of simplicity, we assume that the feasible set defined by $g(u, x)$ is compact, therefore the minimum is attained. Also, in order for (2) not to be point-to-set maps, we focus our attention to one (any) optimizer.

A. Posing the problem

Our point of departure is the observation that the cornerstone of continuous constrained optimization are the Karush-Kuhn-Tucker (KKT) conditions. All local and global minima for problem (1) (satisfying certain constraint qualifications) occur at the so-called “critical points” [8], namely the solution set of the following system:

$$\begin{aligned} \nabla_u J(u, x) + \sum_{i=1}^q \mu_i \nabla_u g_i(u, x) &= 0 \\ \mu_i g_i(u, x) &= 0 \\ \mu_i &\geq 0 \\ g(u, x) &\leq 0. \end{aligned} \quad (4)$$

For the class of problems we consider, the two first relations of the KKT conditions (4) form a *square system of polynomial equations*. Various methods have been proposed in the literature for solving systems of polynomial equations, both numerical and symbolic [9], [10], [11]. Here we consider symbolic methods since our aim is to solve the optimization problem parametrically. We should point out that the underlying philosophy is that we aim at moving as much as possible of the computational burden of solving the nonlinear program (1) off-line, leaving an easy task for the on-line implementation.

B. Off-line vs. on-line computations

The explicit representation of the optimal control law as a state feedback has been successfully investigated for the linear, quadratic and piecewise affine case. Among other advantages of the explicit representation is that one is able to analyze the controller, derive Lyapunov functions [12], perform dynamic programming iterations [13] in an effective way, even compute the infinite horizon solution for certain classes of constrained optimal control problems [14].

Unfortunately, such an explicit representation is not always possible. The enabling factor in the case of linear systems (or piecewise affine systems) is the fact that the KKT system (4) can be solved analytically. In the general polynomial case studied here, we have to solve a system of (nonlinear) polynomial equations. The next best alternative then to an explicit solution is to bring the system in such a form, so that once the parameters are specified, the solution can be extracted easily and fast.

III. THE EIGENVALUE METHOD

In this section we briefly describe the method of eigenvalues ([7], Chapter 2, §4) for solving systems of polynomial equations. This method is used in conjunction with Gröbner bases to perform parametric optimization.

A. Solving systems of polynomial equations

Suppose we have a system of m polynomial equations f_i in m variables u_i

$$\begin{aligned} f_1(u_1, \dots, u_m) &= 0 \\ &\dots \\ f_m(u_1, \dots, u_m) &= 0. \end{aligned} \quad (5)$$

These equations form an ideal $I \in K[u_1, \dots, u_m]$, where K denotes an arbitrary field:

$$I := \langle f_1, \dots, f_m \rangle. \quad (6)$$

The solution points we are interested in are the points on the variety over the algebraic closure \overline{K} of K ,

$$V(I) = \{s \in \overline{K}^m : f_1(s) = 0, \dots, f_m(s) = 0\}, \quad (7)$$

i.e. the set of common zeros of all polynomials in the ideal I . These points can be computed by means of Gröbner bases. An obvious choice would be a projection-based algorithm by means of lexicographic Gröbner bases, see ([15], Chapter 2, §8). Since the computation of a lexicographic Gröbner basis is very time consuming, we focus on a different method.

The first step we take towards solving (5) is computing a Gröbner basis with an arbitrary term-order, e.g. graded reverse lexicographic term-order. We define $G = \{\gamma_1, \dots, \gamma_t\}$ to be this Gröbner basis of I .

B. The generalized companion matrix

Consider a polynomial function $h \in K[u_1, \dots, u_m]$. The Gröbner basis G and the division algorithm make it possible to uniquely write any polynomial $h \in K[u_1, \dots, u_m]$ in the following form:

$$h = c_1(u)\gamma_1 + \dots + c_t(u)\gamma_t + \overline{h}^G, \quad (8)$$

where \overline{h}^G is the unique remainder of the division of h with respect to the Gröbner basis G . The polynomial h can in turn be multiplied with another polynomial function $f \in K[u_1, \dots, u_m]$ and their product expressed as follows:

$$f \cdot h = d_1(u)\gamma_1 + \dots + d_t(u)\gamma_t + \overline{f \cdot h}^G. \quad (9)$$

In the generic case, the ideal I will be *zero-dimensional*, which means that the corresponding *quotient ring*

$$A = K[u_1, \dots, u_m]/I \quad (10)$$

is a finite-dimensional K -vector space ([15], Chapter 5, §2). The quotient ring of an ideal can be thought of as the set of all polynomials that do not belong to the ideal but belong to the underlying ring. Denote with $b = [b_1, \dots, b_l]^T$ the vector of the *standard monomials*. A monomial is standard if it is not divisible by any leading monomial of a polynomial in the Gröbner basis. These standard monomials of G form a basis

$$\mathcal{B} = \{b_1, \dots, b_l\} \quad (11)$$

for the K -vector space A . As a result, every remainder can be expressed with respect to this basis as an inner product

$$r_i = a_i^T \cdot b, \quad (12)$$

where $a_i \in K^l$. We can now define the map $m_h : A \rightarrow A$ as follows: if $\overline{p}^G \in A$, then

$$m_h(\overline{p}^G) := \overline{h \cdot p}^G = \overline{h}^G \cdot \overline{p}^G \in A. \quad (13)$$

The following proposition holds.

Proposition 1: Let $h \in K[u_1, \dots, u_m]$. Then the map $m_h : A \rightarrow A$ is K -linear.

The proof of Proposition 1 can be found in ([15], p. 51). Since A is a finite-dimensional vector space and the map m_h is linear, its representation with respect to a basis of this vector space is given by a square matrix M_h . The $l \times l$ -matrix M_h is called the generalized companion matrix.

C. Computing the companion matrix

To compute the matrix M_h , assume that we have the basis $\mathcal{B} = \{b_1, \dots, b_l\}$ consisting of the standard monomials b_i of the Gröbner basis G . Then, for each one of them, compute the remainder r_i of the polynomial $h \cdot b_i$ with respect to the Gröbner basis G :

$$\overline{h \cdot b_i}^G = r_i, \quad \forall b_i \in \mathcal{B}. \quad (14)$$

All $r_i \in A$ can in turn be expressed as an inner product

$$r_i = a_i^T \cdot b \quad (15)$$

with respect to the basis \mathcal{B} . By collecting all vectors a_i for all basis elements [7], we can construct a representation of the map m_h with respect to basis \mathcal{B} , i.e. calculate the matrix M_h as follows:

$$M_h \equiv [a_{ij}] = \begin{bmatrix} a_1^T \\ \dots \\ a_l^T \end{bmatrix}. \quad (16)$$

Computing the companion matrix is a standard algebraic procedure implemented in various packages, e.g. in Maple 10.

D. Evaluating polynomial functions on a variety

Consider a polynomial function $h \in \mathbb{R}[u_1, \dots, u_m]$. The amazing fact about the matrix M_h is that the set of its eigenvalues is exactly the value of h over the variety $\mathcal{V}(I)$ defined by the ideal I . More precisely, $\mathcal{V}(I)$ is the set of all solution points in complex m -space \mathbb{C}^m of the system (5). The following theorem holds.

Theorem 1: Let $I \subset \mathbb{C}[u_1, \dots, u_m]$ be a zero-dimensional ideal, let $h \in \mathbb{C}[u_1, \dots, u_m]$. Then, for $\lambda \in \mathbb{C}$, the following are equivalent:

- 1) λ is an eigenvalue of the matrix M_h
- 2) λ is a value of the function h on the variety $\mathcal{V}(I)$.

The proof can be found in ([7], p. 54).

To obtain the coordinates of the solution set of (5), we evaluate the functions

$$\begin{aligned} h_1 : u &\longmapsto u_1 \\ &\dots \\ h_m : u &\longmapsto u_m \end{aligned} \quad (17)$$

on the variety $\mathcal{V}(I)$ defined by the ideal I , where u above denotes the vector (u_1, \dots, u_m) . This can be done by means of the associated companion matrices of the functions h_i . The following theorem taken from ([9] p. 22) is the basis for the calculation of these point coordinates.

Theorem 2: The complex zeros of the ideal I are the vectors of joint eigenvalues of the companion matrices $M_{u_1} \dots M_{u_m}$, that is,

$$\mathcal{V}(I) = \left\{ (u_1, \dots, u_m) \in \mathbb{R}^m : \begin{aligned} &\exists v \in \mathbb{R}^m \forall i : M_{u_i} v = u_i v \end{aligned} \right\}$$

It has to be noted that any vector-valued polynomial function $h : \mathbb{R}^m \rightarrow \mathbb{R}$ can be evaluated over a zero-dimensional variety in the same way.

IV. THE ALGORITHM

In this section, we present the proposed algorithm, which consists of two parts: the off-line part, where the generalized companion matrices for the optimization problem are constructed, and the on-line part where this precomputed information is used and given the value of the parameter x , the optimal solution is efficiently extracted.

A. Idea

Under certain regularity conditions, if J^* (defined in (3)) exists and occurs at an optimizer u^* , the KKT system (4) holds at u^* . Consequently, J^* is the minimum of $J(u, x)$ over the semialgebraic set defined by the KKT equations and inequalities (4). These conditions can be separated in a set of inequalities and a square system of polynomial equations. The method of eigenvalues for solving systems of polynomial equations as described in section III can be used for the latter. This method assumes that the ideal generated by the KKT system (4) is zero-dimensional.

By ignoring the inequalities, a superset of all critical points is computed and in a second step, all infeasible points are removed. Finally, among the feasible candidate points those with the smallest cost function value have to be found via discrete optimization. By discrete optimization we mean choosing among a finite set that point, which yields the smallest objective function value.

B. Off-line Part

In $K[u_1, \dots, u_m, \mu_1, \dots, \mu_q]$, where K is the field of rational functions $\mathbb{R}(x_1, \dots, x_n)$ in the parameter x , we define the KKT ideal

$$I_{KKT} = \langle \nabla_u J(u, x) + \sum_{i=1}^q \mu_i \nabla_u g_i(u, x), \mu_i g_i(u, x) \rangle \quad (18)$$

containing all the equations within the KKT-system (4). All critical points for the optimization problem (4) and fixed x are the subset of real points on the KKT-variety

$$\mathcal{V}_{KKT}^{\mathbb{R}} \subseteq \mathcal{V}_{KKT} = \mathcal{V}(I_{KKT}). \quad (19)$$

Using the method described in section III we can compute these by means of the generalized companion matrices.

The algebraic part of the algorithm, i.e the computation of the companion matrices can be done parametrically. For one thing, one could use Gröbner bases computation for the ideal I_{KKT} and try to compute the corresponding

companion matrices M_{u_i} and M_{μ_i} directly. Owing to the structure of the polynomial equations of the KKT -system (18), this problem is very poorly conditioned. The difficulties stem from the fact that the ideal I_{KKT} is by construction decomposable. It contains terms like $\mu_i g_i(u, x)$ which lead to a reducible variety $V(I_{KKT})$.

To overcome this obstacle, we factorize the generators of the Gröbner basis (i.e. the polynomials appearing in relation (18)) and express the ideal I_{KKT} as an intersection of super-ideals $I_{j,KKT}$. The super-ideal $I_{j,KKT}$ denotes the ideal constructed by fixing a subset of p active constraints $\tilde{g}_i(u, x)$ among the set of all q constraints $g_i(u, x)$ – see (18). The corresponding Lagrange multipliers are denoted with $\tilde{\mu}_i$. This leads to

$$I_{j,KKT} = \langle \nabla_u J(u, x) + \sum_{i=1}^p \tilde{\mu}_i \nabla_u \tilde{g}_i(u, x), \tilde{g}_i(u, x) \rangle \quad (20)$$

with the feasibility inequalities

$$\begin{aligned} \tilde{\mu}_i &\geq 0 \\ g_i(x, u) &\leq 0. \end{aligned} \quad (21)$$

Therefore, the ideal I_{KKT} can be expressed as an intersection of $\theta := \#\{\{g_i(u, x)\}_{i=1}^q\} = 2^q$ super-ideals, where θ is the cardinality of the power set of all q constraints. Namely,

$$I_{KKT} = \bigcap_{j=1}^{\theta} I_{j,KKT}. \quad (22)$$

Relations (20) and (21) lead to a large number of super-ideals which are much better numerically conditioned than the original problem, even though they are not necessarily radical. Since many of the sub-varieties $\mathcal{V}(I_{KKT})$ are empty, a Gröbner basis computation for each ideal $I_{j,KKT}$ identifies these infeasible cases in advance and reduces the subsequent companion matrix computations tremendously by discarding them.

The number of solutions over \bar{K} in the non-empty sub-varieties $\mathcal{V}_{j,KKT} = \mathcal{V}(I_{j,KKT})$ can be calculated by means of the Hilbert polynomial ([15], Chapter 9, §3). For zero-dimensional varieties this polynomial reduces to an integer, which is equal to the number of solutions counting multiplicity.

If the sub-variety has only a single solution, the coordinates u_i of the candidate solution can be computed analytically as a *rational* function of the parameters x . In this case, the polynomials in the Gröbner basis from a set of linear equations in the decision variables that can be solved analytically. For all sub-varieties with more than one solution, a companion matrix has to be computed. The result are companion matrices whose entries are rational functions of the parameter x .

Specialization of the parameters gives a map from the field K to the field R of real numbers. If the real parameters are chosen generically enough, then the given Gröbner basis remains a Gröbner basis, but for special choices of the parameters some trouble may arise. For instance, it may happen that a specialization leads to zero denominators.

To handle this case, comprehensive Gröbner bases can be used [16]. The parametric computation is guaranteed to be correct only if the sequence of leading coefficients of the result and the sequence of greatest common denominators removed in the computations are nonzero [16]. If ordinary methods such as Buchberger’s algorithm are used to compute Gröbner bases, these issues have to be kept in mind.

A summary of the off-line algorithm appears in Algorithm 1.

Algorithm 1 *Off-line Part:*

Input: Objective function $J(x, u)$ and constraints $g_i(x, u) \leq 0$.

Output: Set of feasible sub-varieties $\mathcal{V}_{j,KKT}$ with their generalized companion matrices $M_{u_{j,i}}$ and $M_{j,\tilde{\mu}_i}$, or an explicit function $u_{j,i}^*$ for their candidate optimizer.

- 1: **for all** combination of active and inactive constraints **do**
 - 2: construct $I_{j,KKT}$
 - 3: calc. Gröbner basis G_j for $I_{j,KKT}$
 - 4: **if** $G_j = \langle 1 \rangle$ **then**
 - 5: discard the super-ideal
 - 6: **else**
 - 7: calculate number of solutions of $\mathcal{V}_{j,KKT}$ by means of the Hilbert polynomial
 - 8: **if** $\#\mathcal{V}_{j,KKT} = 1$ **then**
 - 9: Express all $u_{j,i}^*$ as rational functions in the parameter x
 - 10: **else**
 - 11: Compute generalized companion matrices M_{j,u_i} and $M_{j,\tilde{\mu}_i}$ for all decision variables u_i
 - 12: **end if**
 - 13: **end if**
 - 14: **end for**
 - 15:
 - 16: **return:** M_{j,u_i} and $M_{j,\tilde{\mu}_i}$, resp. $u_{j,i}^*$ and $\tilde{\mu}_{j,i}$
-

C. On-line Part

In order to evaluate the point coordinates of the KKT sub-varieties, we need to compute eigenvectors and eigenvalues for the companion matrices. Generally, eigenvalue computation cannot be done parametrically. The parameter x has to be fixed to a numerical value and this computation is done on-line.

Given the precomputed generalized companion matrices M_{j,u_i} and $M_{j,\tilde{\mu}_i}$ (resp. an explicit expression for all sub-varieties with linear Gröbner basis) for all possible feasible combinations of active and inactive constraints, the on-line algorithm takes the value of the parameters x to compute the optimum J^* and the optimizer u^* . The three main steps of the algorithm are:

- 1) calculate all critical points
- 2) remove infeasible solutions
- 3) find the feasible solution u^* with the smallest objective function value $J^* = J(u^*)$.

Since all companion matrices have been computed parametrically, the remaining part that has to be done is linear algebra. For every non-empty sub-variety $\mathcal{V}_{j,KKT}$, a set of right eigenvectors $\{v\}$ is computed for the companion matrices M_{j,u_i} of the j -th sub-variety, see Theorem 2. Because all companion matrices for a sub-variety $\mathcal{V}_{j,KKT}$ commute pairwise, they form a commutative sub-algebra within the non-commutative algebra of $l \times l$ matrices, where l is the companion matrix dimension (11), see also [7]. Therefore, it suffices to calculate the eigenvectors for a single arbitrary matrix in this sub-algebra, because they all share the same eigenvectors. To avoid computational problems, we choose a matrix $M_{j,rand}$ in this sub-algebra as a random linear combination of the companion matrices associated with the decision variables M_{j,u_i} , i.e.

$$M_{j,rand} = c_1 M_{j,u_1} + \dots + c_m M_{j,u_m} + c_{m+1} M_{j,\tilde{\mu}_1} + \dots + c_{m+p} M_{j,\tilde{\mu}_p}, \quad (23)$$

where $c_i \in \mathbb{R}$ are randomly chosen. This ensures, with a low probability of failure, that the corresponding eigenvalues will all have algebraic multiplicity of one ([7], Chapter 2, §4).

The sets of eigenvectors $\{v\}_j$ can now be used to compute all candidate critical points and their Lagrange multipliers $\tilde{\mu}_{j,k}$ for the sub-variety $\mathcal{V}_{j,KKT}$. To avoid unnecessary computations, we first calculate the candidate Lagrange multipliers $\tilde{\mu}_{j,i}$ for each sub-variety $\mathcal{V}_{j,KKT}$. In this way, complex or infeasible candidate points with $\mu_{j,i} < 0$ for some i can be immediately discarded before the candidate optimizers $u_{j,i}^*$ are computed. For all sub-varieties with cardinality one, the problem of computing the critical points reduces to an evaluation of the precomputed functions.

For all non-discarded candidate solutions, it remains to be checked whether they are feasible, i.e. $g(u_{j,i}^*, x_i) \leq 0$. To achieve that, a set of feasible local candidate optimizers $\mathcal{S} = \{u_{j,i}^*\}$ is initially calculated by collecting all feasible candidate optimizers. After computing the objective function value $J(u_{j,i}^*, x)$ for all candidate optimizers, the optimal solution

$$J^* = \min_{u_{j,i}^* \in \mathcal{S}} J(u_{j,i}^*, x)$$

and the optimizer

$$u_i^* = \arg \min_{u_{j,i}^* \in \mathcal{S}} J(u_{j,i}^*, x)$$

for the optimization problem (1) can be easily obtained via discrete optimization over the finite set \mathcal{S} .

A summary of the on-line algorithm can be seen in algorithm 2.

V. OPTIMAL CONTROL APPLICATION

In this section we first give a description of the model predictive control optimization problem to show the connection of parametric optimization and optimal control.

Algorithm 2 *On-line Part:* Companion matrices M_{u_i} and $M_{\tilde{\mu}_i}$ for all non-empty sub-varieties $\mathcal{V}_{j,KKT}$, resp. explicit expression for cardinality one sub-varieties has to be provided.

Input: Value of the parameter x (state measurement taken in real time).

Output: Optimal cost J^* and optimizer u_i^* .

- 1: **for all** feasible sub-varieties $\mathcal{V}_{j,KKT}$ with $\#\mathcal{V}_{j,KKT} > 1$ **do**
 - 2: specialize parameter x in M_{u_i} and $M_{\tilde{\mu}_i}$
 - 3: calc. a set of common eigenvectors $\{v\}$ for the companion matrix $M_{j,rand}$
 - 4: solve $M_{j,\tilde{\mu}_i} v = \tilde{\mu}_{j,i} v$ to obtain the joint-eigenvalues, i.e. candidates for $\tilde{\mu}_{j,i}$
 - 5: discard all eigenvectors with corresp. $\tilde{\mu}_{j,i} < 0$
 - 6: use the remaining eigenvectors to calc. joint-eigenvalues of M_{j,u_i} to obtain candidates for $u_{j,i}^*$
 - 7: **end for**
 - 8: **for all** feasible sub-varieties $\mathcal{V}_{j,KKT}$ with $\#\mathcal{V}_{j,KKT} = 1$ **do**
 - 9: evaluate $\tilde{\mu}_{j,i}(x)$ for all i
 - 10: **if** $\exists i : \tilde{\mu}_{j,i}(x) < 0$ **then**
 - 11: discard sub-variety $\mathcal{V}_{j,KKT}$
 - 12: **else**
 - 13: evaluate $u_{j,i}^*(x)$
 - 14: **end if**
 - 15: **end for**
 - 16: **for all** evaluated candidate points $\{u_{j,i}^*\}_j$ **do**
 - 17: **if** $g_k(u_{j,i}^*, x) > 0$ **then**
 - 18: discard candidate point $u_{j,i}^*$
 - 19: **else**
 - 20: evaluate $J(u_{j,i}^*, x)$
 - 21: **end if**
 - 22: **end for**
 - 23: compare $J(u_{j,i}^*, x)$ for the calculated candidates $u_{j,i}^*$ and choose optimal J^* and corresponding u_i^*
 - 24: **return:** optimal cost J^* and optimizer u_i^*
-

A. Nonlinear model predictive control

Consider the nonlinear discrete-time system with state vector $x \in \mathbb{R}^n$ and input vector $u \in \mathbb{R}^m$

$$x(k+1) = f(x(k), u(k)) \quad (24)$$

subject to the inequality constraints

$$g(u(k), x(k)) \leq 0, \quad k = 0, \dots, N, \quad (25)$$

where N is the prediction horizon and $g \in \mathbb{R}[x_1, \dots, x_n, u_1, \dots, u_m]^q$ is a vector polynomial function representing the constraints of the problem. We consider the problem of regulating system (24) to the origin. For that purpose, we define the following cost function

$$J(U_0^{N-1}, x_0) = \sum_{k=0}^{N-1} L_k(x(k), u(k)) + L_N(x(N), u(N)),$$

where $U_0^{N-1} := [u(0), \dots, u(N-1)]$ is the optimization vector consisting of all the control inputs for $k = 0, \dots, N-1$ and $x(0) = x_0$ is the initial state of the system. Therefore, computing the control input is equivalent to solving the following nonlinear constrained optimization program

$$\begin{aligned} \min_u J(U_0^{N-1}, x_0) \\ \text{s.t. } x(k+1) = f(x(k), u(k)) \\ g(u(k), x(k)) \leq 0, \quad k = 0, \dots, N. \end{aligned} \quad (26)$$

Forming a vector u of decision variables with $u_k = u(k)$ and renaming $x(0)$, problem (26) is written in the more compact form

$$\min_u J(u, x) \quad \text{s.t. } g(u, x) \leq 0, \quad (27)$$

where $J(u, x)$ is a polynomial function in u and x , $u \in \mathbb{R}^m$ is the decision variable vector and the initial state $x = x(0) \in \mathbb{R}^n$ is the parameter vector. This is exactly problem (1), a nonlinear parametric optimization problem. Our goal is to obtain the vector of control moves u .

B. Illustrative example

In this section we illustrate the application of the proposed method by means of a simple example. The off-line algorithm including the algebraic methods and the case enumeration (22) have been implemented in Maple. A Maple-generated input file is used to initialize Matlab, in order to compute the optimizer on-line.

Consider the Duffing oscillator [17], a nonlinear oscillator of second order. An equation describing it in continuous time is

$$\ddot{y}(t) + 2\zeta\dot{y}(t) + y(t) + y(t)^3 = u(t), \quad (28)$$

where $y \in \mathbb{R}$ is the continuous state variable and $u \in \mathbb{R}$ the control input. The parameter ζ is the damping coefficient and is known (here $\zeta = 0.3$). The control objective is to regulate the state to the origin. To derive the discrete time model, forward difference approximation is used (with a sampling period of $h = 0.05$ time units). The resulting state space model with a discrete state vector $x \in \mathbb{R}^2$ and input $u \in \mathbb{R}$ is

$$\begin{aligned} \begin{bmatrix} x_1(k+1) \\ x_2(k+1) \end{bmatrix} &= \begin{bmatrix} 1 & h \\ -h & (1-2\zeta h) \end{bmatrix} \begin{bmatrix} x_1(k) \\ x_2(k) \end{bmatrix} \\ &+ \begin{bmatrix} 0 \\ h \end{bmatrix} u(k) + \begin{bmatrix} 0 \\ -hx_1^3(k) \end{bmatrix}. \end{aligned}$$

An optimal control problem with prediction horizon $N = 3$, weight matrices

$$Q = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad R = \frac{1}{10}$$

and state-constraints

$$\|x(k+j)\|_\infty \leq 5 \quad \forall j = 1 \dots N$$

leads to the following optimization problem:

$$\begin{aligned} J^* &= \min_{u(k), u(k+1), u(k+2)} \sum_{i=1}^3 [x_1(k+i)x_2(k+i)] Q \begin{bmatrix} x_1(k+i) \\ x_2(k+i) \end{bmatrix} \\ &\quad + \sum_{i=0}^2 u(k+i)Ru(k+i) \\ \text{s.t. } \|x(k+j)\|_\infty &\leq 5 \quad \forall j = 1 \dots N. \end{aligned}$$

Of these twelve constraints there are ten constraints involving $u(k+i)$, which have to be considered during the optimization. As described in section IV the KKT-variety will be split in $2^{\#\{g_i\}} = 2^{10} = 1024$ sub-varieties. For all of them a Gröbner basis needs to be computed. It turns out that only 29 of these are feasible, i.e. having a Gröbner basis different from unity. Only these cases have to be further considered in the online algorithm. Among them there are 24 sub-varieties $\mathcal{V}_{j,KKT}$ with a linear Gröbner basis. For these, a closed form expression for the candidate optimizers $u_{j,i}^*$ can be computed. For the remaining five cases companion matrices have to be computed, requiring eigenvalue computation in the on-line algorithm. These sub-varieties $\mathcal{V}_{j,KKT}$ have five solutions counting multiplicities, i.e. the companion matrices are 5×5 matrices.

The trajectory of the controlled system starting from an initial state of $x_1(0) = 2.5$ and $x_2(0) = 1$ is shown in Figure 1. Figure 2 shows the state-space evolution of the controlled Duffing oscillator and its free response without the controller. In the uncontrolled case, a weak dynamic behavior and a violation of the constraint $x_2(t) > -5$ can be observed.

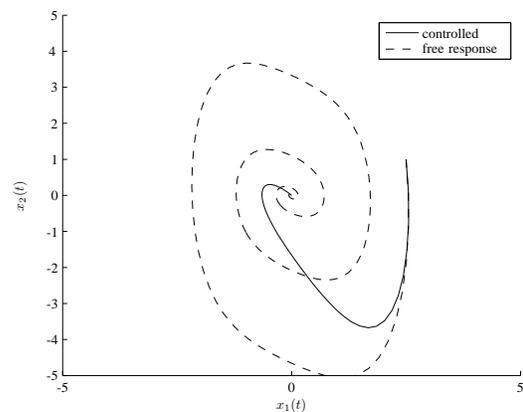

Fig. 1. State-space diagram of the Duffing oscillator

The precomputation of companion matrices and the solutions $u_{j,i}^*$ took less than one minute on a Intel Pentium 3 GHz with 1 GB RAM. The online algorithm needed less than 3.5 s to obtain the global optimum even with a naive brute-force on-line search algorithm for the minimization over the finite set of candidate points. It has to be noted that most of the time of these 3.5 s is consumed by the evaluation of expressions with the Matlab Symbolic Math

Toolbox. An efficient implementation, in C for instance, would be orders of magnitude faster.

VI. CONCLUSIONS AND OUTLOOK

The main contribution of this paper is a new algorithm for nonlinear parametric optimization of polynomial functions subject to polynomial constraints. The algorithm uses Gröbner bases and the eigenvalue method for solving systems of polynomial equations, to evaluate the map from the space of parameters to the corresponding optimal value and optimizer. The algorithm is very general, computationally robust and can be applied to a wide range of problems.

The punchline of the proposed approach is the precomputation of the generalized companion matrices, thus partially presolving the optimization problem and moving the computational burden off-line. The method has been developed with model predictive control in mind. The connection to optimal control problems has been illustrated by applying the method to the Duffing oscillator.

Finally, there is ongoing research on exploiting the structure of specific control problems, including sparseness and genericity assumption relaxation. More specifically, sparse resultant techniques are investigated to compute the companion matrices. Combining this method with recently proposed "Sum of Squares Programming" methods, based on semi-definite representations of finite varieties [18], seems to be a promising direction for further research. Moreover, the integration of the proposed scheme with dynamic programming is also explored.
