Algebraic curves and maximal arcs

A. Aguglia *   L. Giuzzi *   G. Korchmáros *

Abstract

A lower bound on the minimum degree of the plane algebraic curves containing every point in a large point–set $\mathcal{K}$ of the Desarguesian plane $\mathrm{PG}(2, q)$ is obtained. The case where $\mathcal{K}$ is a maximal (k, n)–arc is considered in greater depth.

1 Introduction

In finite geometry, plane algebraic curves of minimum degree containing a given large point–set $\mathcal{K}$ in $\mathrm{PG}(2, q)$ have been a useful tool to investigate combinatorial properties of $\mathcal{K}$.

When $\mathcal{K}$ is the whole point–set of $\mathrm{PG}(2, q)$, a trivial lower bound on the degree of such a plane algebraic curve is $q + 1$. G. Tallini pointed out that this is attained only when the curve splits into $q+1$ distinct lines of $\mathrm{PG}(2, q)$, all passing through the same point. He also gave a complete classification of the absolutely irreducible curves of degree $q + 2$ containing all points of $\mathrm{PG}(2, q)$; see [23, 24] and also [1]. If $\mathcal{K}$ is the complementary set of a line in $\mathrm{PG}(2, q)$, then the bound is q; see [13].

When $\mathcal{K}$ consists of all internal points to a conic $\mathcal{C}$ in $\mathrm{PG}(2, q)$ with q odd, the above lower bound is $q - 1$. The analogous bound for the set of the external points to $\mathcal{C}$ is q. These bounds were the main ingredients for recent combinatorial characterisations of point–sets blocking all external lines to $\mathcal{C}$; see [4, 12].

When $\mathcal{K}$ is a classical unital of $\mathrm{PG}(2, q)$, with q square, the minimum degree d of an absolutely irreducible curve $\mathcal{C}$ through $\mathcal{K}$ is $d = \sqrt{q} + 1$. For non–classical unitals, the best known bound is $d > 2\sqrt{q} - 4$; see [18].

Our purpose is to find similar bounds for slightly smaller, but still quite large, point–sets $\mathcal{K}$, say $|\mathcal{K}| = qt + \alpha$ with $t < c\sqrt[3]{q}$ and $0 \leq \alpha < q$, where c is a suitable constant. Since no combinatorial condition on the configuration of $\mathcal{K}$ is assumed, we are relying on techniques and results from algebraic geometry rather than on the constructive methods used in the papers cited above.

The main result is that if $q > 8t^3 - 12^2 + 4t - 2\alpha + 2$, any plane algebraic curve Γ containing every point of $\mathcal{K}$ has degree $d \geq 2t$. The hypothesis on the magnitude of t can be relaxed to $q > 16t^2 - 24t - 2\alpha + 8$ whenever q is a prime.

In some cases, the bound $d \geq 2t$ is sharp, as the following example shows. Let $\mathcal{K}$ be the union of t disjoint ovals. If q odd, or q is even and the ovals are classical, then $|\mathcal{K}| = qt + t$ and $d = 2t$. The latter case is known to occur when $\mathcal{K}$ is a Denniston maximal arc [10] (or one of the maximal arcs constructed by Mathon and others, [25, 26, 16, 20, 14]) minus the common nucleus of the ovals.

On the other hand, some refinement of the bound is also possible. Let $\mathcal{K}$ be any maximal arc of size $|\mathcal{K}| = qt + t + 1$, that is, a $(qt + t + 1, t + 1)$–arc. Theorem 4.2 shows that if q is large enough comparing to t, then no plane algebraic curve of degree $2t$ passes through every point of $\mathcal{K}$. Therefore, the minimum degree is at least $2t + 1$ for such t and this bound is attained when $\mathcal{K}$ is one of the above maximal arcs.

The case $n = 4$ is considered in more detail. For $q > 2^6$, the minimum degree is 7 and this is only attained when $\mathcal{K}$ is a Denniston arc and the curve Γ of minimum degree splits into three distinct conics with the same nucleus $N \in \mathcal{K}$, together with a line through N.

2 Some background on plane algebraic curves over a finite field

A plane projective algebraic curve Δ is defined over $\mathrm{GF}(q)$, but viewed as a curve over the algebraic closure $\overline{\mathrm{GF}(q)}$ of $\mathrm{GF}(q)$, if it has an affine equation $f(X, Y) = 0$, where $f(X, Y) \in \mathrm{GF}(q)[X, Y]$. The curve Δ is absolutely irreducible if it is irreducible over the algebraic closure $\overline{\mathrm{GF}(q)}$. Denote by N_q be the number of non–singular points lying in $\mathrm{PG}(2, q)$ of an absolutely

irreducible plane curve Δ of degree d. From the Hasse-Weil bound

$$N_q \le q + 1 + (d-1)(d-2)\sqrt{q}. \tag{1}$$

This holds true when singular points of Δ lying in $\mathrm{PG}(2, q)$ are also counted; see [19].

The Stöhr-Voloch bound depends not only on the degree d, but also on a positive integer, the Frobenius order ν of Δ; see [22]. This number ν is either 1 or ε_2, where ε_2 is the intersection number $I(P, \Delta \cap \ell)$ of Δ with the tangent line ℓ at a general point $P \in \Delta$. It turns out that ε_2 is either 2, or a power, say p^h, of the characteristic p of the plane, and is the minimum of $I(Q, \Delta \cap r)$, where Q ranges over the non–singular points of Δ and r is the tangent to Δ at Q. If $q = p$, then $\varepsilon_2 = 2$, and either $\nu = 1$, or $\nu = 2$ and $p = 2$. With this notation, the Stöhr-Voloch bound applied to Δ is

$$2N_q \le \nu(d-3)d + d(q+2). \tag{2}$$

The following algebraic machinery can be used to compute ν. Let $P = (a, b)$ be a non–singular point of Δ such that the tangent line to Δ at P is not the vertical line through P. The unique branch (or place) centred at P has a local parametrisation, also called a primitive branch representation,

$$x = a + t, \, y = b + \varphi(t)$$

where $f(x, y) = 0$ and $\underline{\varphi(t) = b_k t^k + \ldots}$ with $k \ge 1$ is a formal power series with coefficients in $\overline{\mathrm{GF}(q)}[[t]]$; see [21]. Then, ν is defined to be the smallest integer such that the determinant

$$\begin{vmatrix} x - x^q & y - y^q \\ 1 & D_t^{(\nu)}(y) \end{vmatrix} = \begin{vmatrix} a - a^q + t - t^q & b - b^q + \varphi(t) - \varphi(t)^q \\ 1 & D_t^{(\nu)}(\varphi(t)) \end{vmatrix}$$

does not vanish. Here D_t denotes the ν–th Hasse derivative, that is,

$$D_t^{(\nu)}(\varphi(t)) = \binom{k}{\nu} b_k t^{k-\nu} + \ldots.$$

The above idea still works if osculating conics are used in place of tangent lines, and, in some cases, the resulting bound improves (2). Before stating the result, which is the Stöhr-Voloch bound for conics, a further concept from algebraic geometry is needed. Recall that the order sequence of Δ with

3

respect to the linear system Σ_2 of the conics of the plane is the increasing sequence $0, \epsilon_1 = 1, \epsilon_2 = 2, \epsilon_3, \epsilon_4, \epsilon_5$ of all intersection numbers $I(P, \Delta \cap \mathcal{C})$ of Δ with conics at a general point P. The Frobenius Σ_2–order sequence is the subsequence $\nu_0 = 0, \nu_1, \nu_2, \nu_3, \nu_4$ extracted increasingly from the Σ_2–order sequence of Δ, for which the following determinant does not vanish:

$$\begin{vmatrix} x - x^q & x^2 - x^{2q} & y - y^q & xy - x^q y^q & y^2 - y^{2q} \\ 1 & 2x & D_t^{(\nu_1)}(y) & D_t^{(\nu_1)}(xy) & D_t^{(\nu_1)}(y^2) \\ 0 & 1 & D_t^{(\nu_2)}(y) & D_t^{(\nu_2)}(xy) & D_t^{(\nu_2)}(y^2) \\ 0 & 0 & D_t^{(\nu_3)}(y) & D_t^{(\nu_3)}(xy) & D_t^{(\nu_3)}(y^2) \\ 0 & 0 & D_t^{(\nu_4)}(y) & D_t^{(\nu_4)}(xy) & D_t^{(\nu_4)}(y^2) \end{vmatrix}.$$

Assume that $\deg \Delta \geq 3$. The Stöhr-Voloch bound for conics, that is for Σ_2, is

$$5N_q \leq [(\nu_1 + \ldots + \nu_4)(d - 3)d + 2d(q + 5)]. \tag{3}$$

For more on the Stöhr-Voloch bound see [22].

3   Plane algebraic curves of minimum degree through all the points of a given point–set

In this section, $\mathcal{K}$ stands for a set of $qt + \alpha$ points in $\mathrm{PG}(2, q)$, with $0 \leq t \leq q$ and $0 \leq \alpha < q$. Let Γ denote a plane algebraic curve of degree d containing every point $\mathcal{K}$. As already mentioned, $q + 1$ is the minimum degree of a plane algebraic curve containing every point of $\mathrm{PG}(2, q)$. Thus, since we are looking for lower bounds on d, we will only be concerned with the case where $d \leq q$.

A straightforward counting argument gives the following result.

Lemma 3.1. *If $d \leq q$, then $d \geq t$.*

Proof. Since $d \leq q$, the linear components of Γ do not contain all the points of $\mathrm{PG}(2, q)$. Choose a point $P \in \mathrm{PG}(2, q)$ not in any of these linear components. Each of the $q + 1$ lines through P meets Γ at most d distinct points. Thus, $(q + 1)d \geq |\mathcal{K}|$, that is

$$d \geq \frac{qt + \alpha}{q + 1} \geq t - \frac{t}{q + 1}.$$

Since $t < q + 1$, the assertion follows. $\qquad\square$

Our aim is to improve Lemma 3.1. Write $\mathfrak{F}$ for the set of all lines of $\mathrm{PG}(2, q)$ meeting $\mathcal{K}$ in at least 1 point. Set $m_0 = \min\{|\ell \cap \mathcal{K}| : \ell \in \mathfrak{F}\}$ and $M_0 = \max\{|\ell \cap \mathcal{K}| : \ell \in \mathfrak{F}\}$.

Theorem 3.2. *Let Γ be an algebraic plane curve over $\overline{\mathrm{GF}(q)}$ of minimal degree d which passes through all the points of $\mathcal{K}$. If*

$$q > 8t^3 - 16t^2 + 2t + 4 - 2m_0(2t^2 - 5t + 2) + 2M_0(2t - 1), \qquad (4)$$

then $\deg \Gamma \geq 2t$. For prime q, Condition (4) may be relaxed to

$$q > 8t^2 - 16t + 8 - 2\alpha + 2M_0(2t - 1). \qquad (5)$$

Proof. We prove that if $d \leq 2t - 1$, then (4) does not hold. For q prime we show that also (5) is not satisfied. Since Γ is not necessarily irreducible, the following setup is required.

The curves $\Delta_1, \ldots, \Delta_l$ are the absolutely irreducible non–linear components of Γ defined over $\mathrm{GF}(q)$, respectively of degree d_i; $r_1, \ldots, r_k$ are the linear components of Γ over $GF(q)$; $\Xi_1, \ldots, \underline{\Xi}_s$ are the components of Γ which are irreducible over $\mathrm{GF}(q)$ but not over $\overline{\mathrm{GF}(q)}$.

The idea is to estimate the number of points in $\mathrm{PG}(2, q)$ that each of the above components can have.

Let N_i be the number of non–singular points of Δ_i lying in $\mathrm{PG}(2, q)$. Then, (2) holds for any Δ_i. Let $\nu^{(i)}$ denote the Frobenius order of Δ_i. If $\nu = \max\{\nu^{(i)} \mid 1 \leq i \leq l\}$ and $\delta = \sum_{i=1}^{l} d_i$, then

$$2\sum_{i=1}^{l} N_i \leq \sum_{i=1}^{l} \nu^{(i)} d_i(d_i - 3) + (q + 2)d_i \leq \nu\delta(\delta - 3) + (q + 2)\delta. \qquad (6)$$

For q prime, $\nu = 1$; see [22]. Since $\nu^{(i)} = 1$ can fail for $q > p$, an upper bound on $\nu^{(i)}$ depending on d_i is needed. As $\nu^{(i)} \leq \varepsilon_2^{(i)}$, a bound on $\varepsilon_2^{(i)}$ suffices. Since $N_i > 0$ may be assumed, Δ_i has a non–singular point P lying in $\mathrm{PG}(2, q)$. If ℓ is the tangent to Δ_i at P, then

$$d_i = \sum_{Q \in \ell \cap \Delta_i} I(Q, \ell \cap \Delta_i) = I(P, \ell \cap \Delta_i) + \sum_{\substack{Q \in \ell \cap \Delta_i \\ Q \neq P}} I(Q, \ell \cap \Delta_i) \geq \varepsilon_2^{(i)} + m_0 - 1,$$

whence $\nu^{(i)} \leq d_i - m_0 + 1$. From (6),

$$2\sum_{i=1}^{l} N_i \leq \begin{cases} \delta(\delta - 3) + (q + 2)\delta & q \geq 3 \text{ prime.} \\ (\delta - m_0 + 1)\delta(\delta - 3) + (q + 2)\delta & \text{otherwise.} \end{cases} \qquad (7)$$

5

If Δ_i has M_i singular points, from Plücker's theorem $M_i \le \frac{1}{2}(d_i-1)(d_i-2)$. Hence,

$$2\sum_{i=1}^{l} M_i \le \sum_{i=1}^{l}(d_i - 1)(d_i - 2) \le (\delta - 1)(\delta - 2). \tag{8}$$

The number of points of $\mathcal{K}$ lying on linear components r_i is at most $kM_0 \le dM_0$.

For every $\Xi = \Xi_i$, there exists an absolutely irreducible curve Θ, defined over the algebraic extension $\mathrm{GF}(q^\xi)$ of degree $\xi > 1$ of $\mathrm{GF}(q)$ in $\overline{\mathrm{GF}(q)}$, such that the absolutely irreducible components of Ξ are Θ and its conjugates $\Theta_1, \ldots, \Theta_{\xi-1}$. Here, if Θ has equation $\sum a_{kj} X^k Y^j = 0$ and $1 \le w \le \xi - 1$, then Θ_w is the curve of equation $\sum a_{kj}^{q^w} X^k Y^j = 0$. Since Ξ, Θ and the conjugates of Θ pass through the same points in $\mathrm{PG}(2, q)$, from Bézout's theorem, see [17, Lemma 2.24], Ξ has at most θ^2 points in $\mathrm{PG}(2, q)$ where $\theta = \deg \Theta$. Note that $\deg \Xi \ge 2\theta$.

Let N_i' denote the total number of points (simple or singular) of Ξ_i lying in $\mathrm{PG}(2, q)$. From the above argument,

$$\sum_{i=1}^{s} N_i' \le \sum_{i=1}^{s} \theta_i^2 < (\sum_{i=1}^{s} \theta_i)^2 \le \frac{1}{4}(\sum_{i=1}^{s} \deg \Xi_i)^2 < \frac{1}{2}(q+2)\sum_{i=1}^{s} \deg \Xi_i. \tag{9}$$

As,

$$qt + \alpha \le \sum_{i=1}^{l}(N_i + M_i) + kM_0 + \sum_{i=1}^{s} N_i', \tag{10}$$

from (7), (8), (9) and (10) it follows that

$$2(qt+\alpha) \le \begin{cases} 2d^2 - 6d + 2 + 2dM_0 + (q+2)d & q \ge 3 \text{ prime} \\ d^3 - d^2 - 6d + 2 - m_0 d(d-3) + 2dM_0 + (q+2)d & \text{otherwise.} \end{cases}$$

Since $d \le 2t - 1$, the main assertion follows by straightforward computation. $\qquad\square$

Remark 3.3. As $1 \le m_0 \le M_0 \le d$, the proof of Theorem 3.2 shows that Condition (4), and, for q prime, Condition (5), may be replaced by the somewhat weaker, but more manageable, condition $q > 8t^3 - 12^2 + 4t - 2\alpha + 2$ (and $q > 16t^2 - 24t - 2\alpha + 8$ for q prime).

Remark 3.4. As pointed out in the Introduction, Theorem 3.2 is sharp as the bound is attained by some maximal (k, n)-arcs.

Corollary 3.5. *If* Γ *has a component not defined over* $\mathrm{GF}(q)$, *then*

$$\deg \Gamma \geq 2t + 1.$$

Proof. We use the same arguments as in the proof of Theorem 3.2, considering that $\delta < d$. In particular, we have

$$2(qt + \alpha) < d^3 - (4 + m_0)d^2 + (q + 5m_0 + 1)d + (4 - 4m_0 - q) + 2dM_0,$$

which for $d \leq 2t$ proves the assertion. $\qquad\square$

Remark 3.6. Corollary 3.5 implies that a plane algebraic curve of of degree $2t$ containing $\mathcal{K}$ is always defined over $\mathrm{GF}(q)$.

Theorem 3.7. *If the curve* Γ *in Theorem 3.2 has no quadratic component, and*

$$q > \frac{750t^3 - 1725t^2 + 10(10M_0 + 113)t - 184 - 40(\alpha + M_0)}{40}, \qquad (11)$$

then

$$d \geq \frac{5}{2}t.$$

If $q > 5$ *is prime, then Condition* (11) *may be relaxed to*

$$q > \frac{125t^2 + 2(10M_0 - 105)t - 8(\alpha + M_0 - 9)}{8} \qquad (12)$$

Proof. We prove that if $d \leq \frac{5}{2}(t - 1)$, then (11) (and, for q prime, (12)) does not hold. It is sufficient just a change in the proof of Theorem 3.2. Let $\nu_0^{(i)} = 0, \ldots, \nu_4^{(i)}$ be the Frobenius orders of Δ_i with respect to conics. If q is a prime greater than 5, then $\nu_j^{(i)} = j$ for $0 \leq j \leq 4$. Otherwise, set $\nu^{(i)} = \sum_{j=1}^{4} \nu_j^{(i)}$. Since $\nu^{(i)} \leq 2 + \varepsilon_3 + \varepsilon_4 + \varepsilon_5$ and $\varepsilon_5 \leq 2d_i$, we have that $\nu^{(i)} \leq 6d_i - 1$. From (3),

$$5 \sum_{i=1}^{l} N_i \leq \begin{cases} 10\delta(\delta - 3) + (q + 5)2\delta & q > 5 \text{ prime.} \\ (6\delta - 1)\delta(\delta - 3) + (q + 5)2\delta, & \text{otherwise.} \end{cases} \qquad (13)$$

Using the same argument as in (10),

$$\sum_{i=1}^{s} N_i' \leq \frac{1}{4}\left(\sum_{i=1}^{s} \deg \Xi_i\right)^2 < \frac{2}{5}(q + 5)\sum_{i=1}^{s} \deg \Xi_i. \qquad (14)$$

7

Using now (8), (9), (13) and (14) we obtain

$$(qt + \alpha) \leq \begin{cases} \frac{5}{2}d^2 - \frac{11}{2}d + dM_0 + \frac{2}{5}qd + 1 & q > 5 \text{ prime} \\ \frac{6}{5}d^3 - \frac{33}{10}d^2 + \frac{11}{10}d + dM_0 + \frac{2}{5}qd + 1 & \text{otherwise.} \end{cases} \tag{15}$$

Then, (15) does not hold for any q. If q is prime, also (12) is not satisfied. $\qquad\square$

4   Algebraic curves passing through the points of a maximal arc

Remark 3.4 motivates the study of plane algebraic curves passing through all the points of maximal (k, n)–arc in PG$(2, q)$.

In this section $\mathcal{K}$ always denotes a maximal (k, n)–arc. Recall that a (k, n)–arc $\mathcal{K}$ of a projective plane π is a set of k points, no $n + 1$ collinear. Barlotti [9] proved that $k \leq (n-1)q+n$, for any (k, n)–arc in PG$(2, q)$; when equality holds, a (k, n)–arc is *maximal*. A purely combinatorial property characterising a (k, n)–maximal arc $\mathcal{K}$ is that every line of PG$(2, q)$ either meets $\mathcal{K}$ in n points or is disjoint from it. Trivial examples of maximal arcs in PG$(2, q)$ are the $(q^2 + q + 1, q + 1)$–arc given by all the points of PG$(2, q)$ and the (q^2, q)–arcs consisting of the points of an affine subplane AG$(2, q)$ of PG$(2, q)$. Ball, Blokhuis and Mazzocca [5], [6] have shown that no non–trivial maximal arc exists in PG$(2, q)$ for q odd. On the other hand, for q even, several maximal arcs exists in the Desarguesian plane and many constructions are known; see [10], [25], [26], [16] [20], [14]. The arcs arising from these constructions, with the exception of those of [25], see also [16], all consist of the union of $n - 1$ disjoint conics together with their common nucleus N. In other words, these arcs are covered by a completely reducible curve of degree $2n - 1$, whose components are $n - 1$ conics and a line through the point N.

Remark 4.1. From Corollary 3.5, if Γ has a component defined over $\overline{\text{GF}(q)}$ but not over GF(q), and it passes through all the points of $\mathcal{K}$, then its degree d is at least $2n - 1$.

The following theorem shows that the above hypothesis on the components of Γ can be dropped as far as q is sufficiently large.

Theorem 4.2. *For any n, there exists $q_0 \leq (2n - 2)^2$ such that if a plane algebraic curve Γ defined over $\mathrm{GF}(q)$ with $q > q_0$ passes through all the points of a maximal (k, n)–arc $\mathcal{K}$ of $\mathrm{PG}(2, q)$ then its degree d is at least $2n - 1$. If equality holds then Γ has either one linear and $n - 1$ absolutely irreducible quadratic components or $n - 2$ absolutely irreducible quadratic components and one cubic component.*

The proof depends on the the following lemma.

Lemma 4.3. *Assume that Γ is reducible and that the number of its components is less than $n - 1$. Then, the degree d of Γ satisfies*

$$d \geq \sqrt[4]{q}.$$

Proof. We use the same setup as in the proof of Theorem 3.2. This time the Hasse–Weil bound is used in place of the Stöhr-Voloch bound. The number of points of Δ_i in $\mathrm{PG}(2, q)$ is $N_i + M_i$; from (1),

$$M_i + N_i \leq q + 1 + (d_i - 1)(d_i - 2)\sqrt{q}. \tag{16}$$

From (9),

$$\sum_{i=1}^{s} N_i' < (q + 1) + \sum_{i=1}^{s} (\deg \Xi_i - 1)(\deg \Xi_i - 2)\sqrt{q}. \tag{17}$$

If Γ has w components, then

$$w(q+1) + \sum_{i=1}^{s}(\deg \Xi_i - 1)(\deg \Xi_i - 2)\sqrt{q} + \sum_{j=1}^{l}(d_i - 1)(d_i - 2)\sqrt{q} \geq (n-1)q + n. \tag{18}$$

Since $w \leq n - 2$, (18) yields

$$(d - 1)(d - 2)\sqrt{q} \geq q + 2;$$

hence, $d \geq \sqrt[4]{q}$. $\qquad\square$

Proof of Theorem 4.2. Suppose Γ to have degree $d < 2n - 1$. By Remark 4.1, all components of Γ are defined over $\mathrm{GF}(q)$. If Γ is absolutely irreducible, then (1) implies that Γ contains at most $q + (2n-3)(2n-4)\sqrt{q} + 1$ points. However, for q large enough, this number is less than $(n - 1)q + n$; a contradiction.

When Γ has more then one component, denote by t_j the number of its components of degree j. Let u be the maximum degree of such components. Then, $u \leq 2n - 3$ and

$$d = \sum_{j=1}^{u} j t_j \leq 2n - 2.$$

From (1),

$$|\Gamma \cap \mathcal{K}| \leq n t_1 + \sum_{j=2}^{u} t_j (q + (j-1)(j-2)\sqrt{q} + 1) = \left(\sum_{j=2}^{u} t_j \right) q + c\sqrt{q} + d,$$

where

$$c = \sum_{j=2}^{u} t_j (j-1)(j-2), \qquad d = n t_1 + \sum_{j=2}^{u} t_j.$$

Both c and d are independent from q; therefore,

$$n - 1 = \lim_{q \to \infty} \frac{|\Gamma \cap \mathcal{K}|}{q} = \sum_{j=2}^{u} t_j. \tag{19}$$

Hence,

$$2(n-1) = 2\sum_{j=2}^{u} t_j \leq t_1 + \sum_{j=2}^{u} j t_j = d.$$

Since $d \leq 2n - 2$, by Lemma 4.3, for $q > (2n-2)^4$ the curve Γ should have at least $n - 1$ components. This would imply that either $u = 2$, $t_1 = 1$, $t_2 = (n-1)$ or $u = 3$, $t_1 = 0$, $t_2 = (n-2)$, $t_3 = 1$. In particular, in both cases $d = 2n - 1$. $\qquad\square$

Remark 4.4. As mentioned in the Introduction, case $d = 2n-1$ in Theorem 4.2 occurs when $\mathcal{K}$ is a Denniston maximal arc [10] (or one of the maximal arcs constructed by Mathon and others, [25, 26, 16, 20, 14]). This result may not extend to any of the other known maximal arcs; they are the Thas maximal $(q^3 - q^2 + q, q)$–arcs in $\mathrm{PG}(2, q^2)$ arising from the Suzuki–Tits ovoid of $\mathrm{PG}(3, q)$; see [25]. In fact, 22 is the minimum degree of a plane curve which passes through all points of a Thas' maximal $(456, 8)$–arc in $\mathrm{PG}(2, 64)$; see [3].

5 Maximal arcs of degree 4

From Theorem 4.2, for $q > 6^4$, a lower bound on the degree of an algebraic curve Γ passing through all the points of a maximal arc $\mathcal{K}$ of degree 4 is 7. Our aim is to prove in this case the following result.

Theorem 5.1. *Let $\mathcal{K}$ be a maximal arc of degree 4 and suppose there exists an algebraic plane curve Γ containing all the points of $\mathcal{K}$. If $\deg \Gamma = 7$, then Γ consists of three disjoint conics, all with the same nucleus N, and a line through N.*

Proof. From Theorem 4.2, the curve Γ splits either into one irreducible cubic and two irreducible conics or into three irreducible conics and one line r. These two cases are investigated separately.

Let C denote any of the above conics of nucleus N. We show that every point of $C' = C \cup \{N\}$ lying in $\mathrm{PG}(2, q)$ is contained in $\mathcal{K}$: in fact, if there were a point $P \in C' \setminus \mathcal{K}$, then there would be at least $\frac{q}{4}$ lines through P external to $\mathcal{K}$. All these lines would meet C' in $\frac{q}{4}$ distinct points, which, in turn, would not be on $\mathcal{K}$. Hence, Γ would have less than $3q + 4$ points on the arc $\mathcal{K}$, a contradiction.

Now assume that Γ splits into a cubic $\mathcal{D}$ and two conics C_i, with $i = 1, 2$. Denote by N_i the nucleus of C_i and set $\mathcal{X} = C_1 \cup C_2 \cup \{N_1, N_2\}$. Since $|\mathcal{X}| \leq 2q + 4$, there exists a point $P \in \mathcal{K} \setminus \mathcal{X}$. Obviously, $P \in \mathcal{D}$. Every line through P meets $\mathcal{K}$ in four points; thus, there is no line ℓ through P meeting both C_1 and C_2 in 2 points; otherwise, $|\ell \cap \mathcal{X} \cap \mathcal{K}| = 4$ and $|\ell \cap \mathcal{K}| \geq 5$, a contradiction. Hence, there are at least $q - 1$ lines through P meeting $\mathcal{D}$ in another point P'. There are at most 5 bisecants to the irreducible cubic curve $\mathcal{D}$ through any given point $P \in \mathcal{D}$, namely the tangent in P to $\mathcal{D}$ and, possibly, four other tangents in different points to $\mathcal{D}$ passing through P. Hence, there are $q - 6$ lines through P meeting $\mathcal{D}$ in three points. If this were the case, $\mathcal{D}$ would consist of at least $2(q - 6) + 6$ points, which is impossible. Therefore, we may assume that Γ splits into three conics, say C_1, C_2, C_3, with nuclei N_1, N_2, N_3, and a line r.

Recall that, as seen above, the nuclei of all the conics belong to $\mathcal{K}$. Now we show that at least one nucleus, say N_1, lies on the line r. Since Γ is a curve containing $\mathcal{K}$ of minimum degree with respect to this property, there is at least a point P on $r \cap \mathcal{K}$ not on C_1. Each line through P is a 4–secant to $\mathcal{K}$ hence, it meets $\mathcal{X}$ in an odd number of points. If $P \neq N_1$, then the number of lines through P meeting $\mathcal{X}$ in an odd number of points is at most
Figure 1: Case 1 in Theorem 5.1

Figure 2: Case 2 in Theorem 5.1

15, which is less than $q+1$ for $q \geq 2^4$, a contradiction. Actually, all the nuclei N_i lie on r. In fact, suppose that $N_j \notin r$ for $j \in \{2,3\}$. Then, $N_j \in C_s$, with $s \neq 1, j$ and the line $N_1 N_j$ joining N_1 and N_j is tangent to C_1 and C_j. Consequently, $N_1 N_j$ meets C_s in another point different from N_j that is, it is a 5–secant to $\mathcal{K}$, again a contradiction.

We are left with three cases, namely:

(1) $N_1 \neq N_2 \neq N_3$, $C_i \cap C_j = \{A\}$ for any $i \neq j$ and $A \in N_1 N_2$.

(2) $N_i = N_j$, $N_j \neq N_s$, $N_i \in C_s$, $C_i \cap C_j = \emptyset$, with $i, j, s \in \{1,2,3\}$.

(3) $N_1 = N_2 = N_3$ and $C_i \cap C_j = \emptyset$ for $i \neq j$.

We are going to show that cases (1) and (2) do not actually occur.

Figure 3: Case 3 in Theorem 5.1

12

Lemma 5.2. *Let C_1, C_2 be two conics with a common point A but different nuclei N_1, N_2. If $A \in N_1 N_2$ then there is a line s with $A \in s$ and $s \neq N_1 N_2$ such that for any point on $s \setminus (C_1 \cup C_2)$ there passes a line ℓ with*

$$|\ell \cap (C_1 \cup C_2 \cup \{N_1, N_2\})| \geq 3.$$

Proof. Let (X, Y, Z) denote homogeneous coordinates of points of the plane $\mathrm{PG}(2, q)$. Choose a reference system such that $A = O = (0, 0, 1)$ and the line joining N_1 and N_2 is the X–axis. We may suppose C_i to have equation

$$\alpha_i X^2 + XY + \beta_i Y^2 + \lambda_i YZ = 0,$$

where $\alpha_i, \beta_i, \lambda_i \in \mathrm{GF}(q)$ and $i = 1, 2$.

Since both C_i are non–degenerate conics, we have $\alpha_i \neq 0$ and $\lambda_i \neq 0$. Furthermore, $\lambda_1 \neq \lambda_2$ as the nuclei N_1 and N_2 are distinct.

Denote by $\mathfrak{T}(x)$ the trace of $\mathrm{GF}(q^2)$ over $\mathrm{GF}(q)$; namely $\mathfrak{T}(x) = x + x^q$. If $\mathfrak{T}((\alpha_1 \lambda_2 + \alpha_2 \lambda_1)(\beta_1 \lambda_2 + \beta_2 \lambda_1)) = 0$, then the two conics C_1 and C_2 have more than one point in common, which is impossible. Hence, $\mathfrak{T}(\alpha_1 \lambda_2 + \alpha_2 \lambda_1)(\beta_1 \lambda_2 + \beta_2 \lambda_1)) = 1$; in particular, $\beta_1 \lambda_2 \neq \beta_2 \lambda_1$.

A generic point P_m^i of $C_i \setminus \{A\}$ has homogeneous coordinates

$$P_m^i = \left(\frac{\lambda_i m}{\alpha_i m^2 + m + \beta_i}, \frac{\lambda_i}{\alpha_i m^2 + m + \beta_i}, 1 \right),$$

with $m \in \mathrm{GF}(q) \setminus \{0\}$. Consider now a point $P_\varepsilon = (0, \epsilon, 1)$ on the Y–axis, with $\varepsilon \in \mathrm{GF}(q) \setminus \{0, \frac{\lambda_1}{\beta_1}, \frac{\lambda_2}{\beta_2}\}$. The points P_m^1, P_t^2 and P_ε are collinear if and only if

$$\begin{vmatrix} \dfrac{\lambda_1 m}{\alpha_1 m^2 + m + \beta_1} & \dfrac{\lambda_1}{\alpha_1 m^2 + m + \beta_1} & 1 \\ \dfrac{\lambda_2 t}{\alpha_2 t^2 + t + \beta_2} & \dfrac{\lambda_2}{\alpha_2 t^2 + t + \beta_2} & 1 \\ 0 & \varepsilon & 1 \end{vmatrix} = 0,$$

that is

$$\alpha_1 \lambda_2 \varepsilon m^2 t + \alpha_2 \lambda_1 \epsilon m t^2 + \varepsilon(\lambda_2 + \lambda_1) m t + (\varepsilon \lambda_1 \beta_2 + \lambda_1 \lambda_2) m + (\epsilon \lambda_2 \beta_1 + \lambda_1 \lambda_2) t = 0. \tag{20}$$

Equation (20) may be regarded as the affine equation of a cubic curve $\mathcal{D}$ in the indeterminate m and t. Observe that $(0, 0, 1) \in \mathcal{D}$. The only points at infinity of $\mathcal{D}$ are $Y_\infty = (0, 1, 0)$, $X_\infty = (0, 1, 0)$ and $B = (\frac{\lambda_1 \alpha_2}{\lambda_2 \alpha_1}, 1, 0)$.

13

Therefore, $\mathcal{D}$ does not split into three conjugate complex lines. Thus, by [17, Theorem 11.34] and [17, Theorem 11.46], there is at least one affine point $T = (\overline{m}, \overline{t}, 1)$ on $\mathcal{D}$ different from $(0, 0, 1)$.

Since $\mathfrak{T}((\alpha_1\lambda_2 + \alpha_2\lambda_1)(\beta_1\lambda_2 + \beta_2\lambda_1)) = 1$, the line $m = t$ is a 1–secant to $\mathcal{D}$ in $(0, 0, 1)$; hence, the point T is not on this line.

This implies that, for any given $\varepsilon \in \mathrm{GF}(q) \setminus \{0\}$, there exist at least two distinct values $\overline{m}$, $\overline{t} \in \mathrm{GF}(q) \setminus \{0\}$ satisfying (20). Hence, $P^1_{\frac{1}{m}}$, $P^2_{\frac{1}{t}}$ and P_ε are collinear and the line $P^1_{\frac{1}{m}}P^2_{\frac{1}{t}}$ meets $C_1 \cup C_2 \cup \{N_1, N_2\}$ in at least three points. $\qquad\square$

From Lemma 5.2, in case (1) the set $C_1 \cup C_2 \cup \{N_1, N_2\}$ cannot be completed to a maximal arc just by adding a third conic $\mathcal{C}_3$, together with its nucleus N_3, since, in this case, there would be at least a 5–secant to $C_1 \cup C_2 \cup C_3 \cup \{N_1, N_2, N_3\}$. Hence, case (1) is ruled out.

Lemma 5.3. *Given any two disjoint conics C_1, C_2 with the same nucleus N, there is a unique degree–4 maximal arc containing $\mathcal{X} = C_1 \cup C_2$.*

Proof. There is a line r in $\mathrm{PG}(2, q)$ external to $\mathcal{X}$, since, otherwise, $\mathcal{X}$ would be a 2–blocking set with less than $2q + \sqrt{2q} + 1$ points, which is a contradiction; see [8].

Choose a reference system such that $N = O = (0, 0, 1)$ and r is the line at infinity $Z = 0$. The conics C_i, for $i = 1, 2$, have equation:

$$\alpha_i X^2 + XY + \beta_i Y^2 + \lambda_i Z^2 = 0, \tag{21}$$

where $\alpha_i, \beta_i, \lambda_i \in \mathrm{GF}(q)$ and $\mathfrak{T}(\alpha_i\beta_i) = 1$.

Since both C_i are non–degenerate, $\lambda_i \neq 0$. We first show that, $\lambda_1 \neq \lambda_2$, as C_1 and C_2 are disjoint. We argue by contradiction. If it were $\lambda_1 = \lambda_2$, then we could assume $\alpha_1 \neq \alpha_2$; in fact, if $\alpha_1 = \alpha_2$ and $\lambda_1 = \lambda_2$, the linear system generated by C_1 and C_2 would contain the line $Y = 0$; thus their intersection would not be empty. Let now

$$\gamma = \sqrt{\frac{\beta_1 - \beta_2}{\alpha_1 - \alpha_2}};$$

hence,

$$\alpha_1\gamma^2 + \gamma + \beta_1 = \alpha_2\gamma^2 + \gamma + \beta_2,$$

and the line $X = \gamma Y$ would meet the two conics in the same point

$$P = \left(\gamma\big(\tfrac{\lambda_1}{\alpha_1\gamma^2 + \gamma + \beta_1}\big)^{\frac{1}{2}}, \big(\tfrac{\lambda_1}{\alpha_1\gamma^2 + \gamma + \beta_1}\big)^{\frac{1}{2}}, 1\right),$$

contradicting $C_1 \cap C_2 = \emptyset$.

We also see that $\alpha_1 \lambda_2 \neq \alpha_2 \lambda_1$ and $\beta_1 \lambda_2 \neq \beta_2 \lambda_1$, since, otherwise, the points

$$P = (\sqrt{\tfrac{\lambda_1}{\alpha_1}}, 0, 1) = (\sqrt{\tfrac{\lambda_2}{\alpha_2}}, 0, 1), \quad Q = (0, \sqrt{\tfrac{\lambda_1}{\beta_1}}, 1) = (0, \sqrt{\tfrac{\lambda_2}{\beta_2}}, 1)$$

would lie on both conics.

Let now C_3 be the conic with equation

$$\frac{\alpha_1 \lambda_2 + \alpha_2 \lambda_1}{\lambda_1 + \lambda_2} X^2 + XY + \frac{\beta_1 \lambda_2 + \beta_2 \lambda_1}{\lambda_1 + \lambda_2} Y^2 + (\lambda_1 + \lambda_2) Z^2 = 0.$$

Set

$$\nu = \frac{(\alpha_1 \lambda_2 + \alpha_2 \lambda_1)(\beta_1 \lambda_2 + \beta_2 \lambda_1)}{\lambda_1^2 + \lambda_2^2}.$$

The collineation H of $PG(2, q)$ given by the matrix

$$\begin{pmatrix} a^{-1} & 0 & 0 \\ 0 & a & 0 \\ b & c & 1 \end{pmatrix},$$

where $a = \sqrt{\frac{\alpha_1 \lambda_2 + \alpha_2 \lambda_1}{\lambda_1 + \lambda_2}}$, $b = \sqrt{\frac{1 + \alpha_1 / a^2}{\lambda_1}}$ and $c = a \sqrt{\frac{\beta_1 + \beta_2}{\lambda_1 + \lambda_2}}$, maps the conics C_i, $i = 1, 2$, to

$$\overline{C}_2^i : X^2 + XY + \nu Y^2 + \lambda_i Z^2 = 0,$$

and C_3 to

$$\overline{C}_2^3 : X^2 + XY + \nu Y^2 + (\lambda_1 + \lambda_2) Z^2 = 0.$$

If it were $\mathfrak{T}(\nu) = 0$, then $\overline{C}_2^1$ and $\overline{C}_2^2$ would share some point in common on the line at infinity. Hence, $\mathfrak{T}(\nu) = 1$. In particular, $\overline{C}_2^1$, $\overline{C}_2^2$ and $\overline{C}_2^3$ together with their common nucleus O, form a degree–4 maximal arc $\mathcal{K}$ of Denniston type; see [10], [2] and [20, Theorem 2.5].

It remains to show the uniqueness of $\mathcal{K}$. We first observe that $\mathcal{X}$ is a $(0, 2, 4)$–set with respect to lines of the plane. No point lying on a 4–secant to $\mathcal{X}$ can be added to $\mathcal{X}$ to get a degree–4 maximal arc.

Take $P \notin \mathcal{X}$ and denote by u_i with $i = 0, 2, 4$, the number of i–secants to $\mathcal{X}$ through P, that is the number of lines meeting $\mathcal{X}$ in i points. The lines through P which are external to $\mathcal{X}$ are also external $\mathcal{K}$ and the converse also holds. Therefore, when $P \notin \mathcal{K}$, we have $u_0 = \frac{1}{4} q$. From

$$u_0 + u_2 + u_4 = q + 1,$$

15

$$2u_2 + 4u_4 = 2q + 2,$$

also $u_4 = \frac{1}{4}q$. Hence, no point $P \notin \mathcal{K}$ may be added to $\mathcal{X}$ to obtain a maximal arc of degree 4. $\square$

Finally, Lemma 5.3 shows that case (2) does not occur. $\square$
