(Dated: November 13, 2018)

Feshbach's projection formalism in the particle-hole model space leads to a microscopic description of scattering in terms of the many-body self-energy. To investigate the feasibility of this approach, an optical potential for ^{16}O is constructed starting from two previous calculations of the self-energy for this nucleus. The results reproduce the background phase shifts for positive parity waves and the resonances beyond the mean field. The latter can be computed microscopically for energies of astrophysical interest using Green's function theory.

I. INTRODUCTION

The Feshbach's theory of the optical potential [1] provides a tool to describe the scattering of nucleons from nuclei. In its original form, the full Hilbert space is partitioned in a subspace that contains only one particle added to a particular state of the core nucleus. This includes the elastic scattering states and the nuclear orbits unoccupied by the target's nucleons. The resulting optical potential can be thought as an effective interaction that accounts for the effects of the degrees of freedom of the excluded space —such as the overall antisymmetrization of the wave function, excitations of the target or breakup channels. The complexity of these effects makes the *ab initio* calculation of the optical potential a very difficult task. The choice of working in the space of one particle plus a core is shared by several theories of nucleon-nucleus scattering. Examples are the cluster model [2], folding potential [3] and shell model embedded in the continuum [4]. All these techniques have been successfully applied to scattering processes.

A conceptually different approach consists in extending the scattering space to include both a particle on top of the nuclear core and the possibility of propagating a hole excitation. In the following, we will refer to this as the particle-hole (*ph*) Hilbert space. Mahaux and Capuzzi [5] and Jennings and Escher [6] have shown that applying the Feshbach's formalism to this space leads to an optical potential that is the usual many-body self-energy defined in Green's function theory [7, 8]. The properties of using the self-energy as an optical potential have been discussed by Mahaux and Sartor in Ref. [9]. The solutions of the scattering equation above (below) the Fermi energy are the overlap wave functions between the core and the eigenfunctions of the systems with $A+1$

($A-1$) nucleons. For particle states these are the same wave functions as obtained in the original Feshbach approach [1]. The fact that states with $A-1$ particle are included in the formalism does not lead to complications in the study of scattering events. Rather, more physical information can be extracted using the self-energy since it also describes the so called 'Pauli forbidden' orbitals, occupied by the nucleons of the target. Correspondingly, the optical potential in the *ph* space is more easily comparable to phenomenological models (based on, e.g., Wood-Saxon wells) [5, 9] since these also describe hole states. It also has better analytical properties than its counterpart in the particle-only space [5, 6]. Finally, the theory of Green's functions provides a natural way to include the effects of the excitations of the core in terms of an expansion in Feynman diagrams [9, 10].

Many-body Green's functions have been applied in the past to study nuclear correlations, with emphasis on the hole part of the one-body spectral function. Recent developments offer the opportunity to obtain sophisticated descriptions of the couplings between particles and collective states using a Faddeev expansion [11, 12]. A similar formalism was already considered in Ref. [13] for the optical potential where, however, the dressing of propagators was disregarded and no application was attempted. The calculations of Refs. [11, 14] account for collective motion near the Fermi level, including the energy regime of interest to nuclear astrophysics. With a variety of exotic isotopes that are involved in stellar processes becoming experimentally accessible in modern radioactive beam facilities, it is important to investigate whether the Green's function approach can be applied to study low-energy nucleon scattering and capture processes.

We have recently considered the self-energy resulting from a recent application of the self-consistent Green's function (SCGF) method to ^{16}O [14] and explored its predictions for proton-nucleus scattering. These results were obtained in a restricted model space, which is not fully appropriate to describe scattering events. However,

FIG. 1: Feynman diagrams representation of the self-energy. The first diagram on the r.h.s. represents the Hartree-Fock like contribution to the mean field. The remaining ones describe core polarization effects in the particle (2p1h) and hole (2h1p) part of the spectrum.

preliminary calculations with only this input gave encouraging results [15]. In this work the self-energy of Ref. [14] is augmented by including the components from outside this model space, as they have been computed in Ref. [16]. We then report on the final conclusions of these exploratory studies.

The model and the details of the calculations are given in Sec. II. The results for elastic scattering and the bound states of ^{17}F are reported in Sec. III and are preceded by a discussion of the different contributions to the self-energy, in Sec. III A. A discussion and our conclusion are given in Secs. IV and V.

II. MODEL

In the SCGF approach it is useful to split the many-body self-energy into three contributions [10, 17], as shown diagrammatically in Fig. 1. There, the double lines represent the exact one-body Green's function, which contains complete information on the particle and hole spectral distributions. The first diagram on the r.h.s. is the direct extension of the Hartree-Fock potential to include the effects of the fragmentation of strength and represents the nuclear mean-field (MF) in the presence of correlations. The remaining contributions split naturally in diagrams containing *at least* two-particle-one-hole (2p1h), describing the system of $A+1$ particles, or two-hole-one-particle (2h1p), corresponding to $A-1$ particles. The irreducible propagators $R^{(2p1h)}$ and $R^{(2h1p)}$ account for the core polarization contributions to the optical potential in the particle and hole spaces, respectively [9]. The separation of Fig. 1 is exact. In Refs. [11, 14], $R^{(2p1h)}$ and $R^{(2h1p)}$ were computed employing a Faddeev expansion that permits the direct coupling of the single-particle motion to collective excitations of the core. These were evaluated in the dressed random phase approximation (DRPA) [18]. The example of a diagram that contributes to $R^{(2p1h)}$ is given in Fig. 2. Since this expansion is based on the fully fragmented single particle propagator—which is generated from the self-energy itself—a self-consistent solution is required.

The nuclear self-energy computed in Ref. [14] was obtained within a model space \mathcal{P} corresponding to the har-

FIG. 2: Example of a diagrammatic contribution included in the Faddeev expansion for $R^{(2p1h)}$ (see Fig. 1). A quasiparticle is coupled to the response function $\Pi^{(ph)}$ that describes the target nucleus. It can also participate in a pairing processes, which is accounted by the two-body propagator $g^{IF,(pp)}$.

monic oscillator wave functions for all orbitals up to the pf shell plus the $g_{9/2}$. A parameter $b=1.76$ fm was employed. This space appears to be large enough to describe the influence of the low energy (long-range) excitations on nuclear fragmentation [12]. However, it requires a proper extension for applications to single particle scattering, as it will be discussed below. The effect of correlations outside this model space were accounted for by employing a G-matrix as an effective interaction, which was derived from the Bonn-C potential [19] according to Ref. [20]. The computation of the G-matrix for positive energies is an outstanding problem which was not attempted there. Therefore, we employed a fixed starting energy of -5MeV in the present work, as the closest reliable choice to the continuum.

At low energies the optical potential is well approximated by a real interaction and $R^{(2p1h)}$ and $R^{(2h1p)}$ can be expressed as discrete sums of poles. Thus, for each given partial wave, lj , the contributions depicted in Fig. 1 can be expressed as

$$\Sigma_{lj}^{MF,Fadd}(k, k') = \sum_{n_\alpha, n_\beta \in \mathcal{P}} \phi_\alpha(k) \Sigma_{lj; n_\alpha, n_\beta}^{MF,Fadd} \phi_\beta^*(k') , \quad (1a)$$

$$\Sigma_{lj}^{(2p1h),Fadd}(k, k') = \sum_{n_\alpha, n_\beta \in \mathcal{P}} \phi_\alpha(k) \left[\sum_{n+} \frac{(m_\alpha^{n+})^* m_\beta^{n+}}{\omega - \varepsilon_{lj}^{n+} + i\eta} \right] \phi_\beta^*(k') , \quad (1b)$$

$$\Sigma_{lj}^{(2h1p),Fadd}(k, k') = \sum_{n_\alpha, n_\beta \in \mathcal{P}} \phi_\alpha(k) \left[\sum_{k-} \frac{(m_\alpha^{k-})^* m_\beta^{k-}}{\omega - \varepsilon_{lj}^{k-} - i\eta} \right] \phi_\beta^*(k') , \quad (1c)$$

where $\phi_\alpha(r)$ are the harmonic oscillator radial functions referring to single particle quantum numbers $\alpha = \{n_\alpha, l_\alpha, j_\alpha, m_\alpha\}$ [38], the first sum runs over all the orbits belonging to the model space and $l_\alpha j_\alpha = l_\beta j_\beta = l j$ since ^{16}O has a 0^+ isoscalar ground state.

The superscript “*Fadd*” indicates that Eqs. (1) represent the results of Ref. [14]. This is the most sophisticated calculation available to date for the self-energy at low-energies that account for the coupling between single nucleons and collective excitations. However, the expansion over a few harmonic oscillator states is not optimal for describing the details of the nuclear surface. Analogously, it misses part of the large momentum components in the optical potential. This is particularly critical for the MF component, which describes the background of the phase shifts. On the contrary, the same nucleus was studied in Refs. [16] employing a spherical box basis that includes all the relevant momentum components. An effective G-matrix, derived for nuclear matter and the Bonn-B potential [19], accounted for the binding due to short-range and tensor correlations. The self-energy, computed only to second order in the perturbation series, neglected most of the collective effects. This approach was applied to obtain the quasihole wave functions associated to the p states occupied in ^{16}O , with sufficiently accurate results to describe the shapes of the $(e, e'p)$ cross sections to those states [21].

In this work, we chose to employ a mixed representation of the self-energy in which the MF components missing in the space \mathcal{P} were extracted from Refs. [16], while the contributions beyond MF computed in Ref. [14] [Eqs. (1b) and (1c)] were retained. To do this the MF self-energy of Ref. [16] was split in two parts,

$$\Sigma_{lj}^{MF,Box}(k, k'; \omega) = \Sigma_{0,lj}^{MF,Box}(k, k'; \omega) + \Sigma_{1,lj}^{MF,Box}(k, k'; \omega), \quad (2)$$

where $\Sigma_0^{MF,Box}$ is the projection onto \mathcal{P} and $\Sigma_1^{MF,Box}$ acts on the excluded space. Two approximations were considered depending on which MF component to employ inside \mathcal{P} . In the first case (I), $\Sigma_1^{MF,Box}$ was added to Eq. (1a). In doing this, we note that the G-matrix used to compute $\Sigma^{MF,Fadd}$ accounts for the extra binding due to the degrees of freedom of the excluded space. Since these are reinserted explicitly by $\Sigma_1^{MF,Box}$, one should also rescale $\Sigma^{MF,Fadd}$ appropriately by a constant, N^I . The second choice (II), consisted in employing both parts of Eq. (2). Also in this case we kept the possibility of tuning the depth of the potential. The complete MF contributions employed in this work are

$$\Sigma_{lj}^{MF,I}(k, k'; \omega) = N_{lj}^I \Sigma_{lj}^{MF,Fadd}(k, k') + \Sigma_{1,lj}^{MF,Box}(k, k'), \quad (3a)$$

$$\Sigma_{lj}^{MF,II}(k, k'; \omega) = N_{lj}^{II} \Sigma_{lj}^{MF,Box}(k, k'), \quad (3b)$$

where the constants N_{lj}^I and N_{lj}^{II} depend of the specific channel and will be discussed below. The full self-energy employed in the calculations is [see Fig. 1]

$$\begin{aligned} \Sigma_{lj}^{*,I(II)}(k, k'; \omega) &= \Sigma_{lj}^{MF,I(II)}(k, k') \\ &+ \Sigma_{lj}^{(2p1h),Fadd}(k, k'; \omega) + \Sigma_{lj}^{(2h1p),Fadd}(k, k'; \omega). \end{aligned} \quad (4)$$

The Dyson equation can be expressed in a Schrödinger-like form, where the self-energy takes the place of a non-local and energy dependent optical potential [$\hbar = c = 1$ and μ is the reduced mass]

$$\frac{k^2}{2\mu} \psi(k) + \int_0^\infty dk' k'^2 \{ \Sigma_{lj}^*(k, k'; E_{cm}) + V_{Coul.}^l(k, k') \} \psi(k') = E_{cm} \psi(k), \quad (5)$$

where $V_{Coul.}^l(k, k')$ in the Coulomb interaction corresponding to a uniformly charged sphere of radius $R_c = 3.1$ fm. This was added to account for the electromagnetic interaction missing in the calculations of Refs. [14, 16]. Due to the non local character of Σ^* , Eq. (5) is conveniently solved in momentum space. In doing this, the long distance part of the Coulomb potential was solved using the Kwon-Tabakin-Lande [22] procedure for bound states and the Vincent-Phatak [23] one for scattering.

Above the Fermi level the eigenvalues of Eq. (5) are related to the spectrum of ^{17}F by $E_{cm}^n = E_n^{17F} - E_{g.s.}^{16O}$. Thus, $E_{cm} > 0$ describes the scattering of protons from

^{16}O while the bound solutions are the overlaps of the ground state of ^{16}O with the corresponding bound states ^{17}F . Analogously, below the Fermi level $E_{cm}^n = E_{g.s.}^{16O} - E_n^{15N}$ and the eigenstates represent the overlaps with ^{15}N . The Dyson equation implies that the bound solutions of Eq. (5) have to be normalized to their spectroscopic factor according to

$$Z_{lj}^n = \int_0^\infty dk k^2 |\psi^n(k)|^2 = \left[1 - \left\langle \tilde{\psi}^n \left| \frac{d\Sigma_{lj}^*}{d\omega} \right| \tilde{\psi}^n \right\rangle \Big|_{\omega=E_{cm}^n} \right]^{-1}, \quad (6)$$

where $\tilde{\psi}^n(k)$ is the solution itself normalized to unity and E_{cm}^n is the corresponding eigenvalue. The asymptotic

lj	$\Sigma^{MF,Fadd}$	$\Sigma^{MF,Fadd}$	$\Sigma^{*,I}$	E_{cm}^{exp} (MeV)

normalization for the unbound solutions is related in the usual way to the flux of incoming particles.

III. RESULTS

Eqs. (3) and (4) include the relevant physics from both the calculations of Refs. [14] and [16]. This self-energy represents a model for the optical potential that acts on the full ph Hilbert space and can give sensible predictions near the Fermi level. However, the two-body realistic interactions alone, as used in these works, cannot reproduce the experimental binding energies and spin-orbit splitting for nuclei with $A \geq 3$ [24, 25]. To obtain these, relativistic effects or three-body forces are required [26]. In this work Σ^* was constrained to reproduce the experimental spectrum in two ways. First, the constants N_{lj}^I and N_{lj}^{II} that affect the depth of the optical potential were chosen to reproduce the corresponding quasiparticle energies. These are the $s_{1/2}$ and $d_{5/2}$ bound states of ^{17}F , its $d_{3/2}$ resonance and the $p_{1/2}$ and $p_{3/2}$ hole states of ^{15}N . Second, complex resonances that do not have a mean field character are generated by the dynamic part of the self-energy. At low energy, most of these couple to only one pole $\epsilon^{i\pm}$ in Eqs. (1b) and (1c). Therefore, we have fitted those poles that could be identified with specific resonances of the $A+1$ system (^{17}F) by imposing that Eq. (5) yields the corresponding experimental energies. We note that a similar approach was already employed in Ref. [14]. This is necessary for the particular case of ^{16}O due to the strong coupling between the single particle spectrum and collective motions, which suggest the need for an improved description of the low-energy structure of this nucleus [12] and more attractive effective interactions [27]. Although, satisfactory results can already be obtained in similar calculations for heavier nuclei [28, 29, 30].

The influence of this fitting procedure on the results is discussed in the following. After calibrating Eqs. (1) and (3) to the spectra of ^{17}F and ^{15}N , the results for

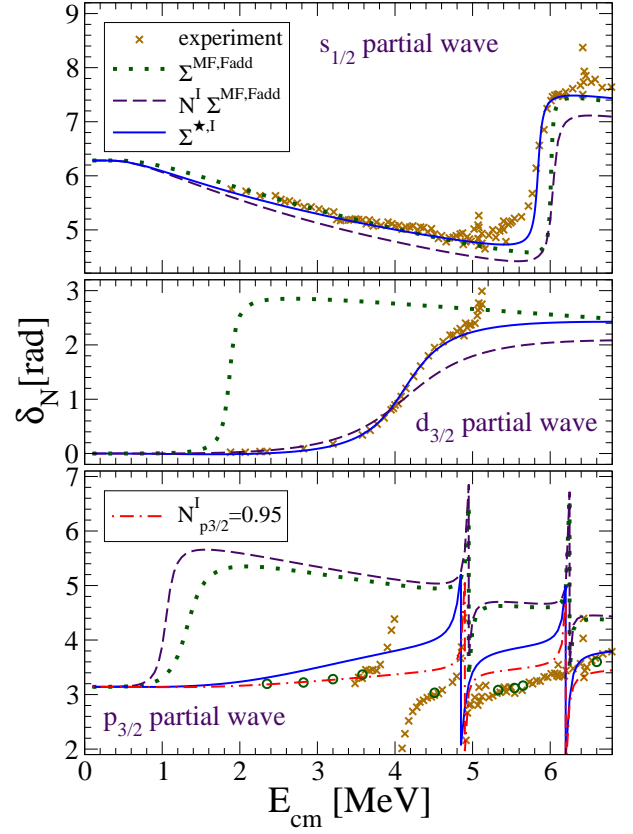

FIG. 3: Phase shifts obtained from the self consistent self-energy of Ref. [14] [Eq. 1] before (dotted lines) and after (dashed lines) correcting the depth of $\Sigma^{MF,Fadd}$ to reproduce the quasiparticle (and quasihole) energies. The full lines are obtained when also the momentum components outside the model space \mathcal{P} are included, Eq. (3a). The $s_{1/2}$, $d_{3/2}$ and $p_{3/2}$ partial waves are shown. For $p_{3/2}$, the dot-dashed line was obtained by fitting $N_{p_{3/2}}^I$ to reproduce the background phase shifts rather than the quasihole energy. The values of the corrections N_{lj}^I are reported in Tab. I. The experimental results are from Refs. [31] (crosses) and [32] (circles).

the scattering phase shifts and the bound single particle wave functions are a prediction of the model.

A. Parameter dependence

To discuss the influence of the different contributions to Eq. (3), the phase shifts for proton scattering have been computed employing different truncations of the mean field self-energy $\Sigma^{MF,I}$. The results are shown in Fig. 3 for three partial waves. The dotted lines were obtained by retaining only the original contribution to the self-energy of Ref. [14]. Thus, neglecting $\Sigma_1^{MF,Box}$ in Eq. (3a) and setting $N_{lj}^I = 1$ for all cases. The results obtained by constraining these constants to generate the proper quasiparticle energies is given by the dashed lines. The full line shows the full results from Eq. (3a), ob-

tained by including also the $\Sigma_1^{MF,Box}$ term and refitting the N_{lj}^I . The values for the quasiparticle energies and the constants N_{lj}^I used are given in Table I

The background contribution to the phase shifts of the $s_{1/2}$ partial wave is described correctly by $\Sigma^{MF,Fadd}$ but not the energy of the bound state. Vice versa, it is possible to constrain the depth of the potential to reproduce the latter but the agreement with the experimental phase shifts is lost. However, both quantities are reproduced if $\Sigma_1^{MF,Box}$ is included. In this case the correction required in the depth of the potential, $N_{S_{1/2}}^I = 1.05$, is less significant than when only $\Sigma^{MF,Fadd}$ is included. A similar trend is seen for the $d_{3/2}$ channel. Reproducing the energy of the single particle resonance with $\Sigma^{MF,Fadd}$ alone requires a sizable change in its depth, while the observed phase shifts are obtained only after including the components outside the space \mathcal{P} . We observe that the expansion of Eq. (1) includes only one harmonic oscillator function for the $d_{3/2}$ wave and two for $s_{1/2}$. With such a restricted space, it is remarkable that the resulting background phase shifts are still obtained somewhat close to the experiment.

A different behavior is found for the $l = 1$ partial waves. The results for $p_{3/2}$ are shown in Fig. 3 (the $p_{1/2}$ case is analogous). In this cases $\Sigma^{MF,Fadd}$ produces a spurious resonance at ~ 1 MeV that is not seen experimentally. Fitting the potential's depth to constrain the quasihole energies of ^{15}N generates a more attractive well, thus worsening the situation. The phase shifts improve upon introducing $\Sigma_1^{MF,Box}$ (full line) but still show a rise of the background with the cm energy, while the experimental results are practically constant. A proper choice of $N_{p_{3/2}}^I$ (and $N_{p_{1/2}}^I$) allows to reproduce the behavior of the phase shifts at the lower energies but results in underbinding the corresponding orbitals in ^{16}O (see Tab. I).

The curves of Fig. 3 have been computed without any shift of the ε^{i+} poles in in Eq. (1b). This gives an idea of the quality the energy spectra obtained adopting the interaction of Ref. [20]. No solutions were obtained that could be interpreted as the $d_{3/2}$ resonances above 5 MeV. The $s_{1/2}$ resonance at ~ 6 MeV was obtained as a coupling of a proton to the first excited state of ^{16}O . Analogously, the two lowest resonances in both $p_{1/2}$ and $p_{3/2}$ can be interpreted as quasiparticle interacting with the first isoscalar 3- and 1- levels of ^{16}O [33].

B. Phase shifts for proton scattering

Figures 4 and 5 compare the phase shifts obtained from both the Self-energies I and II after constraining the quasiparticle energies and resonances to their experimental values. Table II shows the values of the constants N_{lj}^I and N_{lj}^{II} used to obtain these results.

For the positive parity waves the background phase shifts are described equally well by both optical potentials. The potential $\Sigma^{*,II}$ can also describe the nega-

FIG. 4: Phase shifts for positive parity waves obtained from the the self-energies I (dashed lines) and II (full lines). The experimental results are from Refs. [31] (crosses) and [32] (circles).

tive parity waves and it is more accurate for the $p_{1/2}$ case, for which the collective resonances are sharper. In general, the non MF resonances were predicted narrower than the experiment. This is probably related to the lack of momentum components outside the model space \mathcal{P} in Eqs. (1b) and (1c), which were not corrected as for the MF part of the self-energy.

The values of N_{lj}^I and N_{lj}^{II} show that much smaller modifications are needed to force $\Sigma^{*,I}$ to reproduce the quasiparticle energies. This is consistent with the more sophisticated treatment of long-range correlations achieved in Ref. [14]. It is worth noting that the inability to describe both the bound energies and the scattering for the negative parity waves is consistent with the lack of three body forces in the present model, which are needed to reproduce their spin-orbit splitting. On the other hand the results with the MF potential II reproduce reasonably well both the quasihole energies and the phase shifts.

C. Bound overlap wave functions

The overlap wave functions associated to the bound states of ^{17}F are shown in Fig. 6 for the two choices of Eq. (3). The asymptotic behavior in presence of a Coulomb field is given by

$$\psi_{lj}(r) \xrightarrow{r \rightarrow \infty} C_{lj} \frac{W_{-\eta, l+1/2}(r)}{r}, \quad (7)$$

FIG. 5: Phase shifts for negative parity waves obtained from the the self-energies I (dashed lines) and II (full lines). The experimental results are from Refs. [31] (crosses) and [32] (circles).

lj	$\Sigma^{*,I}$	$\Sigma^{*,II}$	E_{cm}^{exp} (MeV)
$d_{3/2}$	1.08	1.24	4.4
$s_{1/2}$	1.05	1.24	-0.1
$d_{5/2}$	1.16	1.29	-0.6
$p_{1/2}$	1.06	1.15	-12.1
$p_{3/2}$	1.07	1.25	-18.5

^a $E_{cm}^{lj} \equiv E_{cm}^{exp}$, except when specified.

where $W_{-\eta, l+1/2}$ is a Whittaker function, η the Sommerfeld parameter and C_{lj} the asymptotic normalization constant (ANC). The spectroscopic factors, ANCs and root-mean-square radii obtained are given Tab. III.

The Self-energy $\Sigma^{*,I}$ predicts larger radii and ANCs than $\Sigma^{*,II}$, which pulls these orbitals more strongly inside the nucleus. At the same time both choices yield the

$\Sigma^{*,I}$	0.931	-82.5	5.86	0.913	1.07	4.01
$\Sigma^{*,II}$	0.921	-73.9	5.55	0.909	0.81	3.70

TABLE III: Spectroscopic factors, ANCs (in $\text{fm}^{-1/2}$) and root-mean-square radii (in fm) for the bound $d_{5/2}$ and $s_{1/2}$ orbitals of ^{17}F .

same spectroscopic factors, implying equal occupancies. The depletion of these orbits is driven by the coupling to long-range collective excitations contained in $\Sigma^{(2p1h),Fadd}$ and $\Sigma^{(2h1p),Fadd}$. An additional quenching is expected from short-range and tensor correlations and was not accounted for in this work. This has been seen to be of about 10% for bound orbitals of several closed shell nuclei [10]. However, what the strength of this reduction should be for loosely bound nucleons, which can be largely localized at radii outside the nuclear surface, has not yet been investigated.

IV. DISCUSSION

In order to include the principals physics ingredients, an improved self-energy was constructed from those ob-

tained by two different calculations of the nucleus of ^{16}O . The effects of coupling a nucleon to collective modes were studied in Ref. [14] but in a restricted model space. The momentum components of the mean field potential outside this space were instead extracted from Ref. [16]. Since these calculations are based on realistic two-body inter-nucleon reactions, the energy spectra cannot be accurately reproduced. Therefore, the model has to be constrained phenomenologically to reproduce the experimental spectra of the nuclei with $A \pm 1$ nucleons. Resolving this situation may require the use of multi-nucleon forces and more appropriate effective interactions.

The present results show that both the inclusion of all momentum components of the particle-hole Hilbert space and a proper treatment of long-range correlations are important to correctly reproduce the mean field optical potential. The coupling of single particle strength to long-range excitations is also responsible for the creation of non mean field resonances. After constraining the prediction for the single particle energies, the phase shifts for the scattering of protons from ^{16}O were obtained in fair agreement with the experimental data, except for the background behavior of the p waves. The difficulties for these waves are accompanied by the issue of explaining the hole spectroscopic factors with the same parity extracted from $(e, e'p)$ experiments [34]. In Ref. [14] the latter were linked to the particularly complicate structure of the low-energy spectrum of ^{16}O and further studies along this line have been initiated in Ref. [12]. It is plausible that the required improvements will resolve both the problems of spectroscopic factors and scattering phase shifts. Similar issues are expected to be beyond the requirements for reproducing most heavier closed shell nuclei [28, 35].

V. CONCLUSIONS

This work investigates the possibility of describing nucleon-nucleus scattering employing the many-body self-energy as an optical potential. This corresponds to applying the Feshbach projection formalism to an Hilbert space containing both particle and hole states.

The present results are a first attempt at computing scattering processes using the many-body Green's functions and required to introduce a certain amount of phenomenological corrections. However, it is shown that predictions for the scattering of nucleons can be obtained working also in the particle-hole space. The present results also give insight into the developments that will be needed to pursue reliable microscopic calculations of the optical potential. We feel that the overall quality of the results can be comparable to other methods applicable at low energies [36, 37] when the role of the missing ingredients, such as short-range correlations, is included. Thus SCGF could be considered as a valid candidate for the study of selected reactions at astrophysical energies.

Acknowledgments

It is a pleasure to acknowledge several useful discussions with J.-M. Sparenberg and W. H. Dickhoff. We also thank Prof. Dickhoff for providing his results from Ref. [16]. We thank the Institute for Nuclear Theory at the University of Washington for its hospitality during the initial writing of the manuscript. This work was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC).
